(Coast Guard Bulletin, No. 14)

WASHINGTON
GOVERNMENT PRINTING OFFICE
1926

TABLE OF CONTENTS

FOREWORD

The following paper has been compiled from a series of lecture notes made by the writer when he took an advanced course on oceanography under Prof. Björn Helland-Hansen, Geo-Physical Institute, Bergen, Norway. Writers of textbooks on oceanography, fail from time to time, due to the rapid growth of this science, to keep pace in print with the newest methods in practice. The need for the appearance of the present treatise is emphasized when it is realized that a complete exposition of the methods elucidated herein has never before, to the writer's knowledge, been collected in a single publication, and the particular hydrographical information, prior to this, has been unavailable short of personal instruction in Europe. Although the illustrations to be found throughout the paper are in most cases examples taken from observations of the International Ice Patrol off Newfoundland, and although the bulletin is intended especially to assist the prosecution of Ice Patrol service, the application of the text is, nevertheless, quite broad in its scope. It is therefore recommended to the attention of all students interested in the subject of physical oceanography.

The foundation upon which this paper rests was first laid down by Prof. V. Bjerknes, (see "Dynamic Meteorology and Hydrography," Carnegie Institution publications, Washington, 1910-11). In the lines of history which record attempts to apply mathematics to the natural sciences this treatise by Bjerknes stands out as one of the most successful and progressive. A perusal of the book can not fail to impress one with the infinite care and exactitude with which the theories have been presented and the exposition developed. It is a model of scientific treatment, but he who is searching for a practical method directly applicable to a hydrographical problem is bound to note the absence of just this sort of pertinent information. Since the time when Bjerknes' theories became recognized by scientists there have been a few oceanographers, especially Helland-Hansen, Nansen, Ekman, and Sandstrom, who have done much to give the formulæ of motion a practical application to the sea. As a result of such development we are now supplied with a scientific method whereby if the temperature and salinity of the ocean are given from several known depths and stations the direction and velocity of the currents even in the deep water off soundings can be computed and mapped. In this connection it may be of interest to know that the currents calculated from the observational data collected in 1922 off the Grand Banks have been found to agree very closely with the drifts of the icebergs of that same year and region.

This paper endeavors to encompass in a general way the foregoing subject with its various aspects. The contents deal with the following: The causes of currents; static consideration of a water mass; dynamics and Bjerknes' theory; and a practical method for mapping currents. Other related subjects discussed are friction; effect of bottom configuration; tides; variations in atmospheric pressures; and the winds. The writer has tried to present a rather technical scientific subject in such a manner that it may easily be understood by the ordinary student. Always there has been the hope that the methods elucidated herein would serve some practical economic service.

I wish to recognize with appreciation the advice and suggestions made with regard to this paper by the curator of the Museum of Comparative Zoology, Harvard University, and the hydrographic engineer, United States Hydrographic Office.

The foreword is not complete unless this place is reserved to express a sincere appreciation and acknowledgment of the untiring, generous assistance and instruction given me in this work by the director of the Geo-Physical Institute, Bergen, Norway. He has in many instances placed even his personal notes at my disposal, and in a hundred other ways has shown an unselfish spirit of cooperation and friendship. As I leave Norway I bid him a fond farewell.

E. H. S.

AUGUST 13, 1925.

A PRACTICAL METHOD FOR DETERMINING OCEAN CURRENTS

Edward H. Smith

THE ORIGIN OF CURRENTS

In order to make a systematic exposition of the circulation taking place in the oceans with especial regard to the origin of currents, we have found it convenient to divide the forces into two general classes: (1) Internal and (2) external.

(1) *Internal forces* appear in an ocean mass whenever any change takes place in the physical character of the water itself; that is, if either the temperature or the salinity varies in the sea then the dynamic equilibrium is upset and a tendency to readjust must follow. The internal system of forces in an ocean are disturbed whenever that mass radiates or absorbs heat; evaporates from the surface; receives additions of fresh water; or suffers internal physical transformation as a result of its turbulent activity. Radiation is simply a gain or loss of heat by the ocean, which tends to vary the temperature of the surface layers. Evaporation tends to vary the salinity of the surface. The ocean receives fresh water from rain, snow, or melting ice. When an ocean mixes internally it alters its physical character within the region of mixing.

(2) *Forces classified as external* and provocative of currents are winds, tides, and variations in atmospheric pressure. The winds we shall divide into two groups, determined primarily by their extent and duration: (*a*) Those winds which by a tangential pressure on the surface of the sea frictionally propagate a pure wind current only; and (*b*) those winds which by virtue of friction drive water particles against boundary surfaces in the sea and give rise to gradient currents. Winds classified as (*b*) are by far the most important of the external forces assisting to maintain the more or less prevailing system of circulation in the oceans.

There are, however, two other forces which are classified as secondary, but only in so far as they tend to deform the components established by (1) and (2). They are, nevertheless, of the utmost importance in the consideration of currents, namely, (*a*) the quasi force due to terrestial rotation which acts simultaneously as soon as a movement as described in paragraph (1) or (2) begins; and (*b*), fric-

tion, that due primarily to land and bottom configuration as it tends to guide and shape the direction as well as to effect the velocity of ocean currents. Friction also is an important factor, arising whenever water particles of dissimilar motions interact among one another. A well-known example of this process is contained in the waters of a mixing zone which lies adjacently inshore of the Gulf Stream and stretches along the American continental slope.

It is difficult, even in such a well-known current as the Gulf Stream, to state which class of forces, internal or external, is the fundamental cause of movement, yet the subsequent forces tending toward alterations of the movements spring from two influences—friction and rotation of the earth. A discussion of some of the foregoing features will assist to a clearer understanding of the entire subject.

STATIC CONSIDERATION OF A WATER MASS

Let us imagine that we can pass a plane vertically downwards through the ocean and can regard a cross section of the water in profile, with a view to studying its static condition, or distribution of mass. If now the water particles could be colored with reference to their relative weights, we would find the lightest water in the surface layers, and the heaviest particles on the bottom. The two fundamental essentials usually determined and which lead to hydrostatic examination are temperature and salinity; once they are found the specific gravity (density) follows as a dependent from convenient hydrographical tables. It is often desirable to speak in terms of specific volume, it being the volume of a body per unit mass, or the reciprocal of the density. If d = density, and v = specific volume, then $v=\frac{1}{d}$. As an example of the contractions which are customarily adopted by practical hydrographers, we may have given, $d=1.02711$; this is written, for the sake of brevity, 27.11. The corresponding value of v in this case is 0.97361, and this is often shortened to a numeral of only three digits, viz, 361. The greater the specific volume at any point the lighter the water is there.

If now we return to our vertical section in the sea and connect all points wherein the water particles have the same specific volume for differences of every 10 units of the latter, we obtain a number of lines called isosteres running throughout the profile. An isoster is a line all points along which represent like values of specific volume; an isosteric surface merely increases the consideration to the two dimensions of an area. An isosteric surface may be visualized as spread out beneath the surface of the sea—an undulating floor whose depth can be determined with the same reality as the more tangible floor of the ocean is sounded out by the hydrographer.

THREE GENERAL STATIC CONDITIONS

There are three general static conditions revealed by vertical sections of the ocean arranged in accordance with a grouping of relative positions of the isosteric surfaces, and with reference strictly to the vertical. (1) The water may be found to have the same density throughout its column when compression is disregarded—i. e., homogeneous as to temperature and salinity. The specific volume in such cases, due to pressure, will necessarily decrease downward, thus it follows that the isosteric surfaces will be arranged solely in dependence with pressure. Such conditions may prevail at the end of winter when vertical convection has attained a maximum influence, or in the cases of strong winds which mix the surface layers, sometimes to a considerable depth. Such a water mass is homothermal and homohaline, and thus presents a consequent neutral

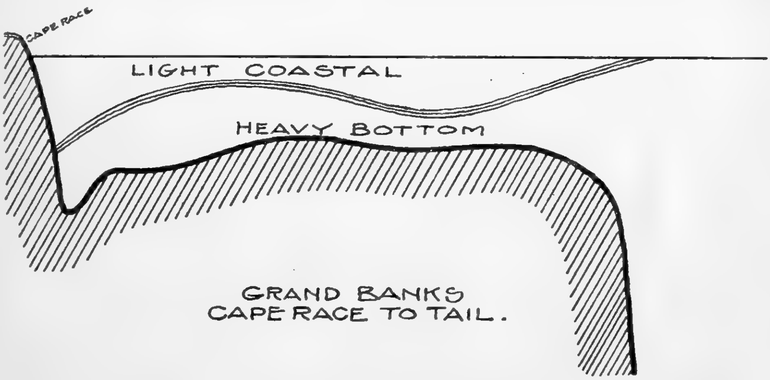

FIG. 1.—A type of stratified water mass found over the Grand Banks south of Newfoundland. The boundary of discontinuity between the two distinct layers is shown by the closely spaced parallel lines

equilibrium vertically. (2) When one homogeneous mass of water lies over another, then the water is in layers and is said to be stratified; it will be found that there are few isosteric surfaces in each layer compared with the number between two adjacent layers. An example of stratification often occurs in the column lying over the Grand Banks, when a cover of heavy water from the slopes is spread over the bottom; above this, and extending to the surface, is a layer of lighter, coastal water, maintained more or less homogeneous by the turbulent effect of the winds. (3) But the most common distribution in the sea is where the density increases proportionally and more or less regularly with the depth. The water in such cases is characterized by numerous isosteric surfaces lying in greater abundance at those levels where transitions of density occur; and this condition is termed stable. A direct measure of the stability of any water column is to be found in the number of isosteric surfaces in excess of that contained in homogeneous water per unit increase

in depth. The sea above the abyssal water, furthermore (with the exception of comparatively restricted places, such as a turbulent mixing zone during a gale), is in a condition pronouncedly stable. Winter cooling of the surface layers, it is true, sets up temporary, vertical, convectional currents, but this condition is short lived when we consider the entire year's span.

DYNAMIC CONSIDERATION OF A WATER MASS

In support of what has just been remarked, we might continue by regarding a vertical section of a stable water mass devoid of circulation. We will find the densest water rests on the bottom of the basin; the lightest water on the surface; and the isosteric surfaces will be exactly horizontal. If now a water particle from a bottom layer be shifted to the surface it will begin to sink to the isosteric sheet from which it was removed. A surface particle, just as truly, if submerged to the bottom will tend to rise and return to its former level. But if a sample be taken from one position to another position, all within the same layer, then there is no force giving rise to its return. It is obvious from this that water particles resist any tendency toward removal from their own particular isosteric sheet, but may move freely within such, if friction does not hinder the motion.

Every motion may be regarded simply as a displacement of masses, therefore a study of various types of distribution of mass in the sea is bound to reveal a vast deal regarding the currents, and in this respect the extreme importance of isosteric bounds governing the movements of the water particles can not be over emphasized. It will be seen, therefore, in the light of further remarks that once we have determined the general contour of the isosteric surfaces we have gained an insight, not only of the direction in which the water is moving, but also a measure of its relative rate of flow. The well-known principle of Archimedes is of great assistance in clarifying the components of the forces due to varying densities.

Let us again regard in profile a vertical section of any body of sea water wherein a distribution of density prevails from which dynamic variations may easily follow. Such a case may arise, as we have pointed out, as an effect of either one of two classes of forces. (See internal and external forces, page 1.) For example, imagine that the ocean has absorbed and mixed heat unevenly during the summer, causing the water to become lighter in a zone over a shallow coastal shelf than the water farther offshore; or perhaps an abnormal percentage of onshore winds have amassed a quantity of light water from the surface layers against a coast. Here, then, class (1) or class (2) forces have produced similar results which can best be examined by recourse to a vertical section normal to the coastal trend.

In Figure 2 the oblique lines are isosteres which have been formed by the intersection of the vertical plane of the section with the isosteric surfaces running through the water mass. The space between any two isosteric surfaces is called an isosteric sheet. The uppermost isosteric sheet on the left-hand side of Figure 2, in wedge-shaped form, bounds the body of lightest water that has accumulated against the coast. Now the water in the deepest portion of this isosteric sheet "A" is specifically lighter than the water *at the same level* in any of the other isosteric sheets, so according to the Archimedian principle this portion of sheet "A" will tend to be driven bodily upwards. The water in the highest portion of sheet "B" is specifically heavier than the water *at the same level* of the inshore sheet, and thus it will be dragged downwards. It is plain to see that

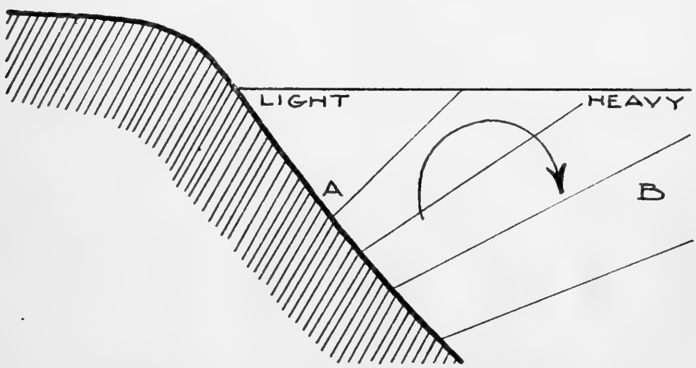

Fig. 2.—A vertical profile of a water mass showing a distribution of light and heavy water and dynamic tendencies which would prevail in such a state

there are forces tending to turn all the isosteric sheets into a horizontal position, and the greater the obliquity of the isosteric surfaces the greater the forces tending toward the leveling process. The water particles themselves, however, as a result of these stresses, will be forced from the thicker portion of the isosteric sheet to the thinner portion of it, the particles tending to keep, for reasons as pointed out in a previous paragraph, wholly within their own respective layer. When the sheets have attained a mean uniform thickness, then the isosteric surfaces have resumed the horizontal, dynamic equilibrium is established and circulation ceases.

The causes provoking currents were divided, it will be recalled, as being due to two classes of forces—viz, internal and external. The distinction between the two rests mainly on the manner in which energy is transmitted to the sea. This conception should be clearly understood.

(1) *Internal class of forces* refers to those agencies, the effects from which appear forthwith to alter the internal character of the water mass itself. This results in varying the distribution of density.

An example has been given when, by the absorption of heat, the water becomes lighter over a coastal shelf in summer.

(2) *External class of forces* can not possibly produce the slightest physical change in the character of the water particles themselves (when the turbulent effect of the wind is disregarded), but either they directly drive the water particles in a current or they deform a water mass that is qualified by boundary conditions. The latter type. similar to (1), tends to vary the distribution of density in the sea; an example has been given in the case of an onshore wind piling up the lighter surface water against a coast.

Thus we may sum up the distinction between the two classified origins of currents—viz, class (1) forces tend to alter the physical character of the sea water while class (2) forces tend either (*a*) to move the water particles in a current or (*b*) to deform eventually a given water mass.

THREE VARIABLES IN THE SEA

It is best to begin by treating the distribution of density in the light of mechanics and physics. We may regard each type as being a field of strain inherent to the mass itself, an effect of stresses, the fields of which in the sea can be treated when expressed in terms of three variables classified as follows: (1) *Gravity*, (2) *pressure*, (3) *specific volume*. Let us examine each one of the three variables separately and their combinations as they lead to dynamic measurement of currents.

First, however, it will be helpful to review some of the fundamentals elementary to a physical science. The three fundamentals in physics are MASS, LENGTH, and TIME, represented by the letters M, L, and T, respectively, and in these terms we may express any form of physical phenomena belonging to the sea. If a length, which is the most tangible of the three, be squared, the result is an area; if cubed, a volume. L = length, L^2 = area, L^3 = volume. If we consider any mass with respect to unit volume we then are determining density, or $q=\frac{M}{L^3}=ML^{-3}$. But inversely, if we contemplate a volume with respect to unit mass, the result is termed specific volume, or $v=\frac{L^3}{M}=L^3M^{-1}$. If we divide a length by a time then it gives rise to a consideration of motion called velocity, or $c=\frac{L}{T}=LT^{-1}$; continuing to divide a velocity by a time (rate of rate of motion) is called acceleration or $a=\frac{c}{T}=\frac{L}{T^2}=LT^{-2}$. A force is that agent which gives motion to a mass. It is expressed in a measurement which considers the mass relative to its rate of change of motion—i. e., acceleration. $K=Ma$; but substituting $a=LT^{-2}$, we get $k=MLT^{-2}$. If M is

unity then we see that the force is equal to the acceleration. The force per unit mass is called the accelerating force. The most common natural force is that of gravity, and is expressed, of course, like other forces, in relation to a mass—e. g., $k = M\,g$—where g is the rate of change of motion (acceleration) of a falling body. Work is consideration of a force and length; $w = k\,L$, but substituting for k its value MLT^{-2}, we get $w = ML^2T^{-2}$. Work may also be spoken of in other forms as energy or potential—viz, the ability to do work. There is another force which enters hydrodynamics—namely, pressure—and it is defined as a force with respect to an area, or $p = \frac{k}{L^2} = ML^{-1}T^{-2}$. The pressure at any depth in the sea is equal to the weight of a column of water of unit depth h with respect to unit area, or $p = qgh$. But substituting $q = ML^{-3}$, $g = LT^{-2}$, and $h = L$, we get $p = ML^{-1}T^{-2}$.

The distribution in space of the value of the variables in the sea—viz., *gravity*, *pressure*, and *specific volume*—may be represented by a series of equiscalar surfaces. Those of gravity are known as equipotential surfaces; those of pressure are called isobaric surfaces; and those of specific volume, isosteric surfaces. The space between two successive equiscalar surfaces is called an equiscalar sheet. If we construct the equiscalar surfaces for unit differences in numerical value of the quantities in question, then we obtain unit scalar sheets. For example, the differences between equiscalar surfaces of potential corresponds to equiscalar units of work.

GRAVITY

Let us contemplate this force apart and alone with respect especially to the envelope of water which surrounds the earth. We may imagine that all the equipotential surfaces throughout an ocean's mass are level, then the surface of such a sea must also be exactly level, and a line to the center of the earth, with an attractive force to that point, called gravity, will plumb exactly perpendicular. Everywhere in such a sea gravity will exert a pull at right angles to the equiscalar surfaces, and the sea surface itself will be an example of a level equipotential plane. Such a motionless state is represented by Figure 3, (*a*), page 8. For the purposes of measuring and coordinating the accelerating force exerted by gravity in the hydrosphere, we shall endeavor to construct a series of concentric equipotential spheroid surfaces, each one separated by equipotential unit sheets. The thickness of such sheets will vary with the latitude, and in our particular subject (the sea) with the depth. The fundamental basis for fixing the relative position of equipotential surfaces in the sea, rests, of course, upon the presence of an attractive force which exists between the earth and the water masses on it.

A free-falling body, regardless of time or its velocity of descent, will be continuously accelerated at the constant rate of about 10 meters per second. For the purpose of measuring forces in the sea we wish to construct a series of coordinate equipotential surfaces, not merely a linear distance apart, but separated by a difference equal to 1 unit of work. Since gravity accelerates a free falling mass about 10 meters, it performs a unit amount of work, not in 10 meters, or even 1 meter, but in one-tenth of a meter, and this unit is recognized as the unit distance fixing equipotential gravity surfaces, always measured along the plumb. A unit of work, therefore, is definitely fixed and unalterable, it being, in the meter-ton-second system of units, the amount of work equivalent to raising 1 ton vertically $\frac{1}{g}$, or about one-tenth of a meter.

The unit work-length—viz, one-tenth of a meter (decimeter)—has been called by V. Bjerknes, who first used it, the dynamic decimeter; the other multiples being named dynamic meter, dynamic centimeter, etc. It is obvious that this new measure has all the equivalents of linear measure but is restricted in its use solely to the vertical. The dynamic depth of any point is not the common linear distance of this point below the surface of the sea, but it is a direct statement regarding the amount of potential or work inherent to that point relative to the sea surface.

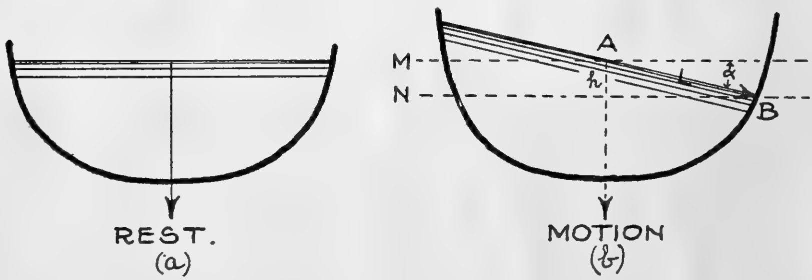

FIG. 3.—The two states of "rest" and "motion" considered with regard to the position of the sea surface. (*a*), "rest," all equiscalar surfaces, including the sea surface are level, and the entire force of gravity is directed as a component perpendicularly downward; (*b*), "motion," the equiscalar surfaces, including the sea surface, are tilted, which gives rise in such surfaces to a component of the force of gravity and causes a movement of the water particles

We have considered a motionless sea, and its equipotential surface. Suppose, on the other hand, we regard a sea surface not level; let us say, raised near the coast by a wind pressing the water masses up the inclined, continental slope. Now the sea surface being no longer level is, by definition, no longer of equal value potentially, and gravity exerts a component in the plane of the sea. Here we have the birth of a current. The size of the component force is directly proportional to the obliquity of the surface, the two conditions, "rest" and "motion," being graphically illustrated in Figure 3.

If D in Figure 3 (*b*) is the distance in dynamic decimeters between two points in the sea, and h is the unit vertical distance in common meters, then $D = g\ h$, where g is the acceleration of gravity. In (*b*), if we know the difference in dynamic depth units (the number of dynamic decimeters) between any two points, A and B in the sea, this number will be the same as the gravity potential released by a unit water mass flowing from A to B. Expressed geometrically we have from the figure, two points A and B between two level surfaces M and N, the two latter of which are h decimeters apart. The angle between line L and the planes M and N is called α

$$w = L \sin \alpha\ \bar{g} = h\ \bar{g} = D.$$

where D = difference between M and N in dynamic decimeters, and α is so small in all cases that $\sin \alpha$ may be put equal to α.

Let us, before passing on to a discussion of pressure, glance at the more exact values of acceleration due to gravity at various points on the earth, and also determine the corresponding values of potential expressed in dynamic measure. The attractive force of the earth, g, increases both with the latitude and with the depth in the sea, therefore the distances between equipotential unit surfaces—i. e., the dynamic decimeters—will be longer at the equator and near the surface of the sea, where g is comparatively small, than at the pole and near the bottom where g is comparatively large. In the meter-ton-second system of units a free falling body will accelerate approximately 9.8 meters in one second, therefore the dynamic decimeter, or unit of gravity potential, will be equal numerically to the reciprocal of this value, or 1.02 common decimeters. Stated inversely one common decimeter equals 0.98 dynamic decimeters. Simply multiplying units by 10 give results in terms of ordinary meters and dynamic meters, both of which are of a magnitude most convenient for practical investigations in hydrodynamics.

PRESSURE

Pressure is defined as a force, the intensity of which may be represented at any depth by the weight of a column of water of unit area extended vertically upwards to the surface. The force of pressure, though present at every point in the ocean, does not actually manifest itself as an active agent until we extend our consideration to two points and the difference of pressure arising. This statement, of course, holds true more or less for all forces, but it seems worth remarking here, as sea pressure, to most people, is an effect difficult to comprehend; yet a difference in pressure, such as exists when a hollow sphere is submerged in the sea, immediately becomes tangible.

Let us take, for example, the motionless ocean in which we constructed a system of equipotential surfaces 1 dynamic decimeter

apart (about one-tenth of a meter) and calculate the pressure per unit area on such a plane at a depth of about 1 decimeter. The pressure of the atmosphere being subject to comparatively slight and compensating variations can be totally disregarded throughout hydrodynamic works. (See p. 45.) We have given by definition values of pressure = weight per unit area =

$$\frac{\text{area, height, density, acceleration of gravity.}}{\text{area}}$$

Since the area values cancel, we have

$$\text{pressure} = h\ g\ \bar{q}.$$

But it has been determined that $g\ h = D$, where D equals 1 dynamic decimeter.
Substituting:

$$p = \bar{q}\ D$$

Now it remains to find a suitable system of units of pressure based upon the value equal to a water column 1 dynamic decimeter high and possessing a mean density q.

The most common example of natural pressure with which we are familiar is that of the atmosphere. It has been a practice, long established, to balance the perpendicular column of the atmospheric envelope against an equal cross-sectional area of mercury. This is a well-known experiment of any physics laboratory in which mercury has come to be adopted because of its great density; other liquids being forced to too great a height by the balance. We employ exactly the same equation, of course, as evolved in the case of a motionless ocean; in fact, we might imagine finding the pressure at various depths in the sea, theoretically, by means of a balanced column of mercury.

It has been found that at 0° C. and 45° latitude at sea level, the normal height to which mercury is forced by the ever pressing air envelope, is 0.76 meters, sometimes termed an "atmosphere." Since the acceleration of gravity at 45° latitude is known, viz, 9.8 meters, and the density of mercury at 0° C. is 13.59, let us calculate the pressure p in meter-ton-second units—i. e., the system upon which previous dynamic figures have been based. Substituting in

$$p = q\ g\ h, \text{ we have } p = 13.59 \times 9.8 \times 0.76 = 101.218.$$

V. Bjerknes has used this quantity of 101.218 as a guide in deciding upon the value ascribable to p. He has selected as a unit suitable for hydrodynamic computations, the nearest integral number of 10 to 101.218, viz, 100, and has called this a bar. A bar is approximately the pressure exerted by a column of water 10 meters in height; therefore the pressure of 1 meter of water is very nearly equal to the

pressure of 1 decibar. We should note the coincidence that 1 meter below the surface the gravity potential is very nearly 1 dynamic meter less, and the pressure 1 decibar more.

$p=\bar{q}\,D$ . . . . in terms of decibar units ---------------------- (a)

$D=\bar{v}\,p$ . . . . in terms of dynamic meter units ---------------- (b)

In order to show the close coincidence existing between dynamic units and pressure units of this system for increasing depth, we may regard the various values for the three arguments, viz, common meters, dynamic meters, and decibars, as they exist in a sea of 0° C. temperature, and 35 per mille salinity.

Decibars	100	200	300	400	500	600	700	800	900	1,000	1,200	1,400	1,600	1,800	2,000
Meters	99	198	298	397	496	595	693	792	891	990	1,187	1,385	1,582	1,779	1,975
Dynamic meters	97	194	292	389	486	583	680	777	874	970	1,164	1,357	1,551	1,744	1,936

It will be seen from the foregoing that under conditions as specified there is a difference of about 1 per cent between a depth expressed in pressure decibars and that expressed in common meters. This difference becomes even smaller under natural conditions prevailing on the earth, and thus being so insignificant, when contemplating the horizontal extension of ordinary sea areas, permits us, with the same number, to express a depth either in common meters or in decibars. The difference between dynamic meters and common meters averages about 2 per cent, and between dynamic meters and decibars about 3 per cent, and these are of a magnitude that can not be disregarded.

The two foregoing equations (a) and (b), in the case of equilibrium, expresses as simply as possible the relation existing between gravity potential, pressure, and specific volume. Thus it follows that we may by (a) find the pressure in decibars at a given dynamic depth, or by (b) the dynamic depth of a certain given pressure.

We have already described the equipotential gravity surfaces and the potential sheets with a thickness of 1 dynamic meter. Now the surfaces of equal pressure are given, called isobaric surfaces, which are separated by isobaric sheets 1 decibar thick. It is seldom that we have under natural conditions a motionless water mass, and so then it will usually be found that isobaric and level surfaces intersect. In other words, an isobaric surface contains varying potentials of gravity, and a level surface, in like manner, contains many baric variations. The intersections of these two surfaces may be considered as lines of the one inscribed on the plane of the other, accordingly as we employ equation (a) or (b). If the lines of intersection are considered inscribed on the level surfaces, they are isobars, and the chart is similar to the ordinary meteorological charts

which show the distribution of pressure. But if we employ equation (b) we must represent the result as dynamic isobaths inscribed on an isobaric surface and drawn—e. g., for unit differences of 5 dynamic millimeters. Such a method of representation corresponds to that of a common topographical chart, but the contour lines on a dynamic chart instead of showing ordinary, linear heights, show levels of equal potential. A dynamic topographical chart of a certain isobaric surface is the most approved method employed in modern dynamic oceanography to map ocean currents.

APPLICATION OF DYNAMIC UNITS

The number of unit equipotential sheets found in an isobaric sheet between two different station verticals represents a certain amount of potential energy existing between the two verticals.

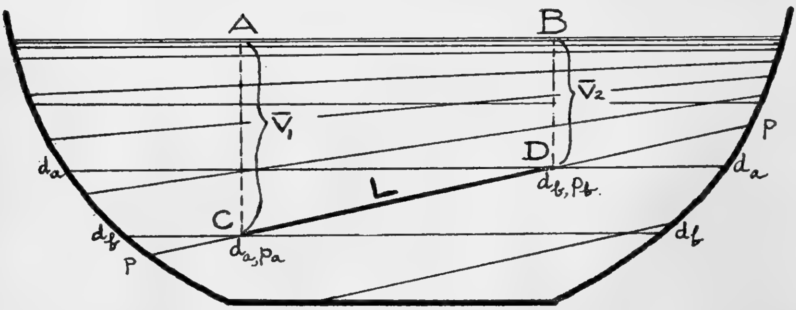

FIG. 4.—A vertical section through a sea basin and including the two stations A and B, with the respective points C and D separated by the distance L. C and D are at a depth of p decibars below the surface

Figure 4 shows a section through a sea basin which includes two stations, A and B. The horizontal lines represent the intersections with some equipotential surfaces, and the oblique lines the intersections with some isobaric surfaces. The dynamic distance from the sea surface to the isobaric surface of p decibars is d_a at station A, and d_b at station B. According to equation (b) we have:

$$d_b = p_b\ \bar{v}_b$$
$$d_a = p_a\ \bar{v}_a$$
$$\text{But } p_a = p_b$$

and therefore

$d_a - d_b = p\ (\bar{v}_a - \bar{v}_b)$ . . . . in terms of dynamic meters ---------- (c)

$d_a - d_b$ represents the difference of potential energy, due to gravity, between the points D and C in Figure 4. This energy may be converted into work, $d_a - d_b = k\,L$, where k is a force and L is the distance between the two points. Hence the force per unit mass due to gravity may be expressed

$$k = \frac{d_a - d_b}{L} = \frac{p(\bar{v}_a - \bar{v}_b)}{L}$$

DEPTH AT WHICH GREATEST OBLIQUITY OF ISOBARIC SURFACES OCCUR

It is important to distinguish where the greatest obliquity of the isobaric surfaces prevail in an ocean mass. Dynamic measurements and pressures have been considered as being laid off from the surface of the sea downwards on the assumption that the sea surface is always level—an equipotential surface. This premise demands considerable revision, as we shall see, in the light of the following facts:

As a result of compiled oceanographic observations, it is well known to-day that the greatest variations in temperature and salinity of the water take place in the upper levels of the sea. In the North Atlantic, for example, below depths of 3,000 meters there is little variation, as we proceed from place to place, in the temperature or the salinity. Now, if we regard two stations with widely differing specific volumes, we shall generally find that their difference decreases more or less rapidly with an increase in depth, and gradually approaches a constant or zero. Where the water is light we shall observe a relatively low pressure in decibars at a certain dynamic depth, or conversely at a given observed pressure in decibars, the dynamic depth will be least where the water is heaviest. In view of this natural state of the ocean, if the sea surface be level, then the obliquity of the isobaric surfaces must increase downwards and the maximum of forces and currents would be relegated to the greater depths, a condition which we know is contrary to fact. It follows alternatively that at an *appreciable* depth below the surface there will generally be a sheet where motion most nearly approaches zero and where isobaric, isosteric, and equipotential surfaces are parallel. It follows, furthermore, that above such a motionless plane, the water, over any given horizontal extent, lies at the greatest height (the surface of the sea highest) at that place where the water is the lightest—i. e., the specific volume the greatest.

We should endeavor to select from a group of observations indicative of a surveyed area an isobaric surface which in itself has the most nearly equal dynamic depths, thereby sounding out a level or motionless plane and which as stated before generally will be found to lie at a relatively great depth beneath the surface of the sea. When employed as a "bench mark" this surface provides a means of measuring the currents which usually are present in the upper levels. The velocities are determined by a comparison of any two dynamic heights measured upwards from the level, isobaric plane to the surface of the sea. Figure 5, page 14, shows in exaggerated form the obliquity of the sea surface, and also the other isobaric surfaces of observation as they lay May 5–7, 1922, south of the Grand Banks, between stations 206 and 201. The state of relative obliquity is based upon the assumption that the maximum depth of observation, the 750 decibar

surface, was a level plane. Other observations in this locality indicate that the 750 isobaric plane, however, is not always level, but a motionless state probably lies at some greater depth. The depth of 750 decibars, nevertheless, approaches most nearly to the level where absence of motion may prevail of any depth of which the International Ice Patrol records; therefore, it has been employed in this paper as an illustration of the most accurate base upon which to calculate surface currents in the vicinity of the Grand Banks.

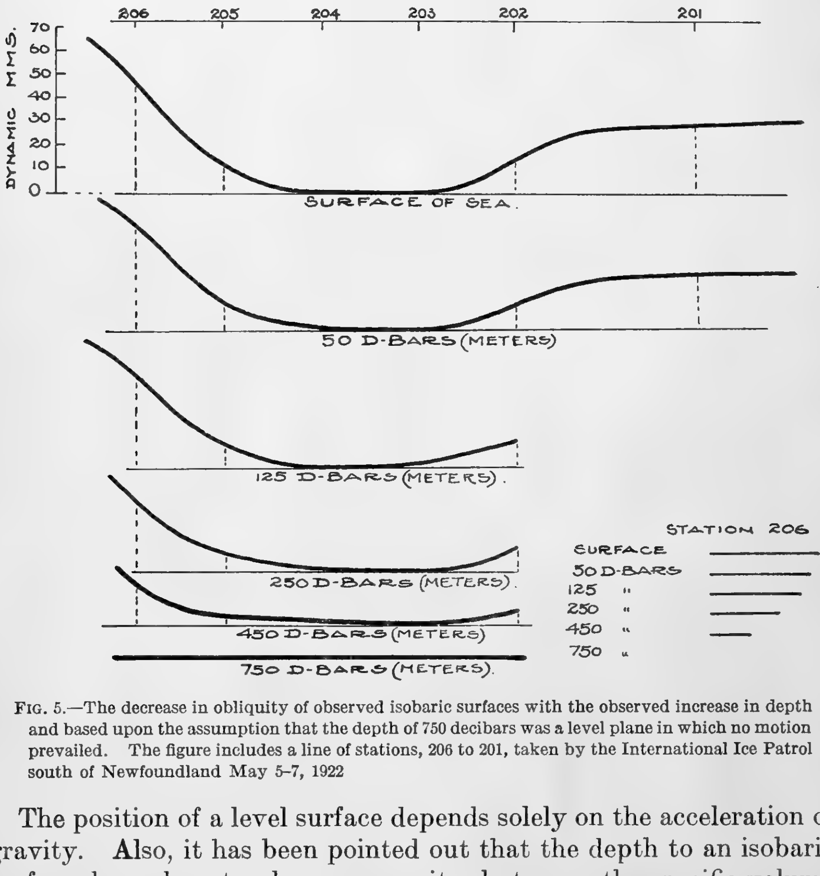

FIG. 5.—The decrease in obliquity of observed isobaric surfaces with the observed increase in depth and based upon the assumption that the depth of 750 decibars was a level plane in which no motion prevailed. The figure includes a line of stations, 206 to 201, taken by the International Ice Patrol south of Newfoundland May 5–7, 1922

The position of a level surface depends solely on the acceleration of gravity. Also, it has been pointed out that the depth to an isobaric surface depends not only upon gravity, but upon the specific volume of the overlying masses. Since we have already discussed gravity, let us now turn to the remaining term, specific volume.

SPECIFIC VOLUME

Pressure per unit area depends upon two variables, gravity and specific volume, but gravity being a more or less constant force, the agency which exerts the greatest influence to vary the pressure throughout the sea is specific volume. Specific volume has been defined as the volume of unit mass of any body. It is simply the

reciprocal of the specific gravity and is chosen in preference to the density because its value leads to the simplest method of dynamic calculations. It is, in such cases, combined directly with other parts of the term pressure, and furnishes a result in terms of gravity potential. (See equation (b), p. 11.)

In the depths of the sea observations are not made directly of specific volume, but it is obtained only after first finding the temperature, salinity, or density at a given temperature, and then correcting for the particular depth below the surface at which the observation was made. The temperature is, of course, a direct instrumental observation. The salinity is calculated ordinarily by determining the chlorine content of the sample and substituting in Knudsen's formula:

$$s = 0.30 + 1.805\ Cl$$

The two foregoing characters of sea water have been tabulated by Knudsen with regard to corresponding values of density, within the range of that normally met in the oceans.

It is vitally necessary in the course of dynamic computations, moreover, to know the specific volume in situ—that is, the actual specific volume as it existed at the particular depth at which it was found. Thus, after the specific volume has been determined from the temperature and salinity, it must be corrected for a third variable, viz, compression. It is easy to appreciate that a mass, even such as water, becomes more and more compressed the deeper down we penetrate beneath the surface. Naturally, the more compressed a body becomes, the denser it grows—i. e., its specific volume becomes increasingly less. The compressibility of sea water is not entirely dependent upon the depth below the surface, but it is also influenced by the temperature (and to a much slighter degree by the salinity) prevailing in the water itself. Generally speaking, the warmer and saltier is a water mass, the less it can be compressed. Investigations have been made regarding the compressibility of sea water at various depths under different combinations of temperature and salinity by Ekman. (cf. Die Zusammendrüeckbarkeit des Meerwassers, etc. Pub. de Constance, Copenhagen, 1908.

In order to construct tables for specific volume in situ, it is necessary to combine the two previous tables—namely, those of Knudsen for temperature and salinity with those of Ekman for compressibility. It is impossible, however, to arrange one convenient and accurate table for specific volume in situ, because of the multitudinous combinations arising between the three variables, viz, temperature, salinity, and compression, as they commonly range in the sea. Direct tablulation, according to V. Bjerknes, would require something like 256,000 pages of 500 numbers each, if intervals of 0.1 degree temperature, 0.01 per mille salinity, and 10 decibars pressure were em-

ployed as arguments. Helland-Hansen and Sandstrom in "Report on the Norwegian Fishery Investigations, Volume II, No. 4, Bergen, 1903," first provided a way to avoid such a ponderous, unwieldly work by calculating, as an initial step, the values of specific volume at frequent depths, and covering the normal range of change in compressibility in an ocean of 0° C., and a salinity of 35 per mille. A correction called the anomaly of specific volume is then added to this first figure, representing the specific volume of any charactered water, but under a similar pressure. According to these arrangements all corrections are embodied in a total of four small handy tables. The details of this ingenious method of tabulation are also described in Bjerknes', "Dynamic Meteorology and Hydrography," Carnegie Institution Publications, 1910–11. Later table groupings have been made and published by Hesselberg and Sverdrup, "Beitrag zur Berechnung der Druckund Massenverteilung im Meere," Bergens Museums Aarbok, 1914–15.

GIVEN TEMPERATURE AND SALINITY—A GRAPHIC METHOD TO FIND DENSITY

The specific volume in situ, as determined by the foregoing tables, is based upon an initial given density, usually found by means of Knudsen's Hydrographical Tables with addendum. There is considerable labor attached to interpolating when there are perhaps several hundred observational records of temperature and salinity which require conversion into density form. The Geo-Physical Institute, Bergen, where the writer spent some time, finds it convenient to facilitate such work by the construction of a graph based upon the three arguments of temperature, salinity, and density, within the range which prevails for the first two in the temperate zones. The method possesses such great advantages over the use of the tables that it is set forth here for the benefit of future investigators who may have to deal with a large number of field observations.

The construction of the graph is based upon the three formulæ of Knudsen:

(1) $s = 0.30 + 1.805\ Cl.$

(2) $\delta_o = -0.069 + 1.4708\ Cl - 0.001570\ Cl^2 + 0.0000398\ Cl^3.$

(3) $\delta_t = \Sigma_t + (\delta_o + 0.1324)\ [1 - A_t + B_t\ (\delta_o - 0.1324)].$

(For d_o, d_t, Σ_t, A_t, and B_t see Martin Knudsen's, "Hydrographical Tables," Copenhagen, 1901.) Density values are plotted as abcissæ, salinity values as ordinates, and isotherm curves, determined in accordance with the fixed relation existing between the three variables, run diagonally across the graph. In order to determine the latter with a sufficient degree of accuracy, it is necessary to fix definitely a

certain minimum number of points, by substituting values in the three given equations. As a first step let us substitute a value of $Cl.$ in the first equation, which will result in the lowest value in the range of salinities which it is desired to span. A few trials indicate that a value of $Cl.$ equal to 17.5 gives a desirable value of s equal to 31.618 per mille, which in turn is substituted in equation (2) furnishing the numeral 25.4025 as the value of δ_0. This again is substituted in equation (3) along with the values for A_t, B_t, and Σ_t for every two degrees change in the range of temperature known to prevail in the particular region which is under investigation. Thus we obtain a series of values for a salinity of 31.618 per mille, and in the same manner, another series of temperature points on the graph using other values of salinity, as shown in Table I:

TABLE I

	Cl	s_1	δ_0	δ_0-1324	δ_0+1324
a	17.5000	31.618	25.4025	25.2701	25.5349
b	18.000	32.520	26.1267	25.9943	26.2591
c	18.700	33.783	27.1462	27.0138	27.2786
d	19.287	34.843	28.0000		
e	19.928	36.000	28.9310	28.7990	29.0638
f	20.482	37.000	29.7390	26.6069	28.8717

The values as tabulated in Table I, upon further substitution, result in the following values as given in Table II:

TABLE II

Temperature (degrees) 2	Densities 3					
	a	b	c	d	e	f
−2	25.458	26.190	27.216	28.076		
0	25.402	26.127	27.146	28.000		
2	25.290	26.008	27.020	27.868		
4	25.124	25.836	26.842	27.863		
6	24.907	25.616	26.614	27.450		
8	24.644	25.348	26.340	27.171		
10	24.337	25.037	26.023	26.849		
12	23.987	24.685	25.665	26.486		
14	23.600	24.292	25.267	26.084		
16	23.173	23.862	24.833	25.646		
18	22.709	23.395	24.362	25.171		
20			23.856	24.662		
21					25.272	26.034
22				24.119	24.995	25.755
23					24.710	25.469
24				23.544	24.417	25.175
25					24.116	24.872

Having determined arguments 1, 2, and 3, we are now provided with data sufficient to fix the construction of a graph which in turn furnishes a rapid means of obtaining density values from given temperatures and salinities.

TABLES FOR CONVERTING DENSITIES INTO SPECIFIC VOLUMES IN SITU

In order to obtain values of specific volume in situ, Hesselberg and Sverdrup have arrived at the following formula:

$$V_{s,\,t,\,p}=1-\frac{\delta_t\,.10^{-3}}{1+\delta_t\,.10^{-3}}+\delta_p+\delta_{s,\,p}+\delta_{t,\,p}.$$

where δ_t = density; δ_p = density correction for pressures; $\delta_{s,\,p}$ = correction for salinity under various pressures; $\delta_{t,\,p}$ = correction for temperature under various pressures; $V_{s,\,t,\,p}$ = specific volume in situ. These four arguments have been arranged in an equal number of tables by Hesselberg and Sverdrup, "Beitrag zur Berechnung der Druckund Masserverteilung im Meere." Bergens Museums Aarbok, 1914–15, Nr. 4. The first table representing the value $10^5.\frac{\delta_t\,.10^{-3}}{1+\delta_t\,.10^{-3}}$, is reprinted herewith, and the three tables for the last three terms have been combined in one table (Table IV), which makes reference much easier and without sacrifice of the requirements of practicality. When employing Tables III and IV in the method of computations as followed on page 32 it is well to note that the values as carried in Table III are from the nature of the equation (shown at the head of this page) of a negative character. In Table IV the corrections for the three factors, viz, pressure, salinity, and temperature, as they affect the specific volume in situ, are combined in accordance with signs as indicated at the head of Table IV. An example of the application of Tables III and IV is given in the computations for two oceanographic stations, 205 and 206, page 28.

Table III

$$10^5.\frac{\delta_t\,.10^{-3}}{1+\delta_t\,.10^{-3}}$$

DISTRIBUTION OF MASS

Information as to the distribution of mass in a free-moving media, such as in an ocean, furnishes a direct insight of the dynamic conditions there. Representation of mass distribution is clearly shown by isosteric lines, which in profile form, after all corrections have been made, including that of compressibility, is called a dynamic section. An example of such is to be seen in Figure 12, page 30, which has been constructed from a group of stations taken by the International Ice Patrol, 1922, and extended in a line across two currents in the ice regions south of Newfoundland.

The importance of the position of isosteric surfaces as an indicator of the motions taking place in a water mass, was pointed out in a previous paragraph. Enlargement of this exposition can be continued hereby regarding such a vertical section where a system of isobaric and isosteric surfaces, by intersection with the vertical plane, divide the latter into a set of parallelograms. If we extend the vision to three dimensions, then the parallelograms take form as a set of tubes.

Since they lie between adjacent isobaric surfaces their continuation must cease only by turning on themselves or by meeting the sides of the basin. V. Bjerknes has given the name "solenoid" to an isobaric-isosteric tube. It is convenient to select as a unit tube one included by isosteric surfaces constructed for intervals of 10^{-5} of specific volume, and isobaric surfaces constructed for intervals of one centibar. Bjerknes has also called attention to the significance of solenoids by stating that the measure of the intensity of forces in a given vertical sectional area is in direct proportion to the number of solenoids running through it. This number depends upon the degree of stability and inclination; the greater the stability and the inclination, the greater the number of solenoids per unit cross-sectional area.

EFFECT OF EARTH ROTATION ON OCEAN CURRENTS

Dynamic tendencies of water particles have been discussed purely as indicated by mass distribution; now the behavior of such phenomena are traced in the form of actual motion on, and as qualified by, the veering surface of a rotating sphere.

In order to understand the effect of earth rotation on currents, we might begin by studying very closely the absolute movement of a fixed body at the pole of a rotating sphere and another similar body on the equator. It will soon be perceived that the former enjoys a pure centric movement while the latter has a pure translatory motion, and any intervening point partakes a centric-translatory path. Bodies at rest relatively to the globe, as also the surface of the earth itself, are, strictly speaking, under a phase of centric and translatory motion, the relation between the two depending upon the geographical latitude. This phenomenon is very difficult to comprehend, since all of our senses are trained to accept the earth and resting bodies as a stationary base, and these remarks in so short a space, can hope to touch generalities only. Those who are interested in a detailed exposition of the subject are referred to Krummel (cf., Handbuch der Ozeanographie, vol. 2). Also Humphreys (cf., "Physics of the Air." 1920).

As long as all bodies remained in fixed relations, a state of "rest" may be said to prevail, by virtue of the fact that no variations from the relative positions exist. But distinction immediately arises whenever any free motion whatsoever, relatively to the earth, is introduced. At any other point on the earth's surface than along the equator, due to the element of centricity previously described, divergence takes place between the straight path of a particle due solely to inertia, and the movement of other particles held fast to the surface of the earth and carried around with it as it rotates. This fact was proven years ago when the straight line of motion possessed by Focault's pendulum swinging to and fro soon revealed

that the surface of the earth was veering to the left in the Northern Hemisphere. It is more natural to regard the inverse perspective—that is, the earth and resting bodies as stationary—then the paths of inertia are apparently being continuously deflected to the right. Earth rotation exerts no effect on a water mass free from circulation relatively to the earth, but on the other hand no true conception of free-moving currents can be had unless this great influence is considered. In this connection it should be realized, from the foregoing remarks on motion on a rotating sphere, that currents can not be traced solely to a provocative force at their source, but they are only to be observed as a resultant of a force, the effect of which is constantly being deformed by the earth "sliding" beneath it. If a water particle moves solely due to inertia, without being acted upon by any force, it will follow a course "cum sole" (clockwise with the sun). As the latitude increases the tendency which drives a water particle to the right of its course becomes more and more intensified, and the faster it moves, the greater becomes the quasi force tending to deflect it.

In order to study this quasi force in detail, it is convenient, similar to the procedure employed in the investigation of varying mass and pressure (see fig. 4, p. 12) to regard the circulation of the curve in a plane between any two verticals. We may take, for example, stations A and B (fig. 6, p. 22), with their verticals AC and BD forming the plane ABDC. The development of an equation for expressing the rotation effect demands too great a digression into mathematics and is not warranted here, but it has been evolved by V. Bjerknes as equal to

$$2\omega \frac{ds}{dt}$$

where ω represents the angular velocity of the earth, viz, 0.0000729; and is the projection of the closed curve of the circulation, as illustrated here by the rectangle ABDC, on the equatorial plane; and $\frac{ds}{dt}$ represents the rate of change of the projection on the plane of the equator.

In Figure 6, page 22, if the curve of circulation ABDC, which is being investigated, is projcted upon the equatorial plane, it is evident that a change of the proportional area is effected only by components normal to the plane and not by those tangential to it. Also the vertical movements can be considered negligible, since they are insignificant as compared with horizontal magnitudes. Helland-Hansen and Sandstrom have, by this means, found the value for Bjerknes' equation in terms of the projection on the plane of the sea surface

$$\frac{ds}{dt} = \frac{d\sigma}{dt} \sin \phi$$

where σ is the projection on the sea surface, and ϕ is the geographical latitude. Substituting this new value for $\frac{ds}{dt}$ we have

$$2\omega \frac{d\sigma}{dt} \sin \phi \text{ ---------------------- (d)}$$

$$\text{but } \frac{d\sigma}{dt} = A'B'D''C'' = (c_0 - c_1), L \text{ where}$$

c_0 = velocity per second in a given horizontal plane.
c_1 = velocity per second in another horizontal plane.
L = distance between stations.

Substituting in (d) for the new value $\frac{d\sigma}{dt}$ we have

$$2\omega \sin \phi \ (c_0 - c_1) L \text{ ------------------ (e)}$$

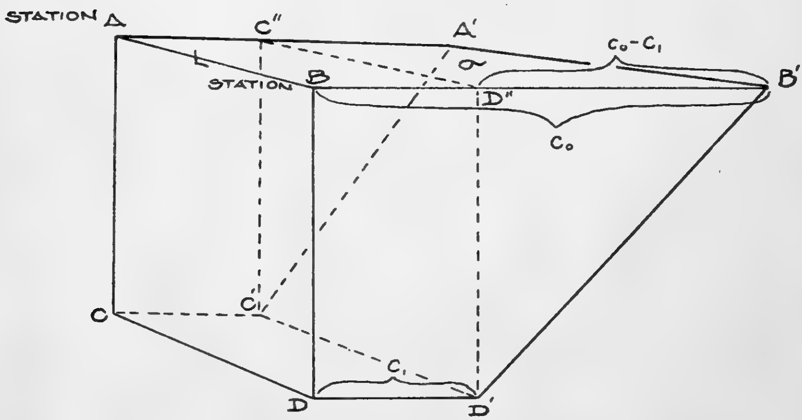

FIG. 6.—Lines AA′ and BB′ represent the velocity of the surface current, or c_0, per unit T; CC′ and DD′ indicate the velocity of the current at a greater depth, or c_1. The difference in the velocity of the two movements is equal to D″ B′, or $c_0 - c_1$. The movement is assumed to be normal to the vertical plane ABDC, which is passed through the two stations A and B. Area C″ D″ B′ A′, indicated by the symbol σ, represents the difference in the change of areas per change of T, projected on the sea surface and developed by the progression of the two lines AB and CD with the respective velocities c_0 and c_1

Thus by (e) we are furnished with an expression for the effect of terrestial rotation in terms of the latitude; the distance between stations; and the difference in velocity of the current between any two levels. It is easy to see that if we are able to find some point along the verticals where zero velocity prevails, then we have a means of expressing the real velocity. It is customary to extend the investigations to depths where it is believed motionless water lies, and then $c_1 = 0$, and c_0 is the true velocity on the surface. (See p. 13 regarding the obliquity of isobaric surfaces.)

RESOLUTION OF FORCES IN GRADIENT CURRENTS

It has been pointed out in the previous section that the effect of rotation tended to deflect currents to the right in the Northern Hemisphere. This quasi force can be represented by a vector of a certain magnitude which lies 90° to the right of the current. If we let the line AB, Figure 7, represent a more or less steady current of sufficient size to give the water particles a translatory path, then the effect of terrestial rotation may be shown by the line AC, Figure 7. Since the rotation effect is always present, as represented by the line AC, it follows that the only condition under which a current can flow, stream, and be preserved, is fulfilled by a force or system of forces (when friction is disregarded) which acts equal and opposite to AC, and is represented in Figure 7 as the line AE. AE illustrates the force characterized as due to varying mass and pressure, and is measured by the equated values of the three variables—*gravity*, *pressure*, and *specific volume*. It is, moreover, the impelling force of such gradient currents (i. e., currents resulting from an obliquity of equiscalar surfaces); and it should be remarked here that this driving force is to be sought not back along the current's course to a river-like source, but it always lies on the right hand stretching along the entire extent of flow. The Gulf Stream, for example, as it follows a general path around the periphery of the North Atlantic basin, is energized along the shores of Europe (a fact which is just as vital for its propagation) as well as receiving propulsion in the Caribbean. Where the velocity is relatively great, there the dynamic gradient is correspondingly steep, and without such energy distributed around Atlantic slopes, the Gulf Stream would directly disintegrate. If we divide gradient currents into the forces which combine to give flow to the water particles we have (1) dynamic inequalities due to varying densities, and (2) the effect of earth rotation, each one of which acts in a plane perpendicular to the path of the moving water particles. Since (1) and 2) lie in the same plane, and inasmuch as the acceleration of the closed curve ABDC (see fig. 6, p. 22) (represented by the line AC, fig. 7) has been determined, let us now regard the rectangle ABDC with respect to acceleration tending in the opposite direction. (Shown as line AE, fig. 7.)

Fig. 7.—A diagrammatic front view showing the relative positions of the major elements belonging to a steady gradient current. AB represents the path of flow of the water particles; AE, the position of the forces due to Archimedean tendencies which impel the current; and AC the position of the quasiforce of earth rotation in a plane 90° to the right (in the northern hemisphere) of the direction of the current

It will be recalled that the force of varying mass and pressure tending to produce acceleration by equation (b) is equal to

$$D = p\,\bar{v}$$

and the accelerating force in a closed curve ABDC between stations A and B, in the plane formed by the verticals AC and BD, is equal to

$$d_a - d_b = p\ (\bar{v}_a - \bar{v}_b).$$

Since AC equals AE, (fig. 7, p. 23), we may substitute (e) and obtain the following:

$$d_a - d_b = p\ (\bar{v}_a - \bar{v}_b) = 2\ \omega \sin \phi\ (c_0 - c_1) L \text{ - - - - - - - - - - - (f)}$$

Thus finally we are furnished with an expression which includes the forces due to the distribution of mass and pressure tending to accelerate a current moving on a rotating earth, and moreover, it is formed of terms which readily lend themselves to the requirements of practical oceanography.

THE PRACTICAL METHODS AND FORM OF COMPUTATIONS GENERALLY FOLLOWED IN DYNAMIC PHYSICAL OCEANOGRAPHY

We may now continue by describing the manner in which the unknown terms of (f) are determined by observational data secured from a closed curve ABDC in a plane formed by verticals AC and BD, between stations A and B. First we shall regard the forces tending to

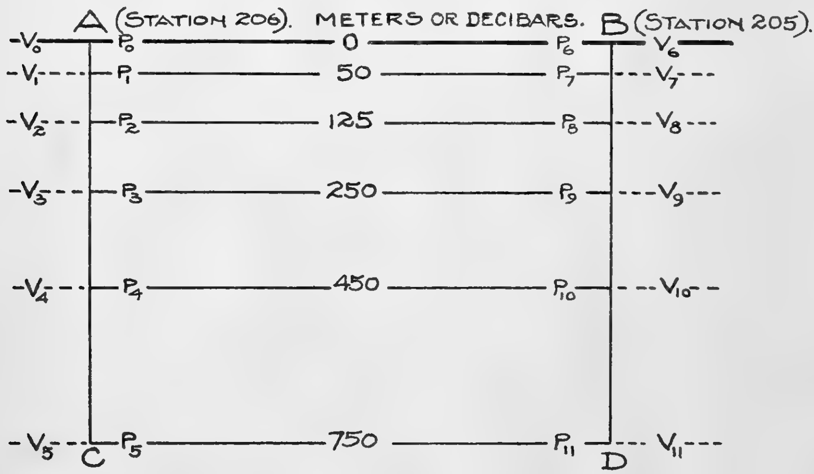

FIG. 8.—Two verticals A and B at stations 206 and 205, respectively, and with the observed values of v and p at depths expressed in decibars or meters as follows: 0, 50, 125, 250, 450, and 750

accelerate the particles as a result of varying degrees of stability in the water columns of any given area. The abstract exposition, furthermore, has been supplemented by a practical example wherein stations A and B are replaced by stations 206 and 205, respectively. (See computations, p. 28.) These stations were taken by the International Ice Patrol in 1922, the sectional line forming approximately a right angle with the northern edge of the Gulf Stream south of the Grand Banks.

It is assumed that the specific volumes in situ have been calculated from the tables, as based upon the temperature and salinity records from the observed depths, viz, 0, 50, 125, 250, 450, and 750 meters. The values of p are, for all practical purposes, equal to the depth in meters—that is, at a depth of 750 meters the pressure is 750 decibars (see p. 11). In order to compute as accurately as possible the value of D (the dynamic depth) for the vertical AC, it is necessary to consider the change at frequent depths which occurs in the value of v (the specific volume). In order to comprehend the method of mathematical computation customarily followed, e. g., p. 28, it will be helpful to regard Figure 9.

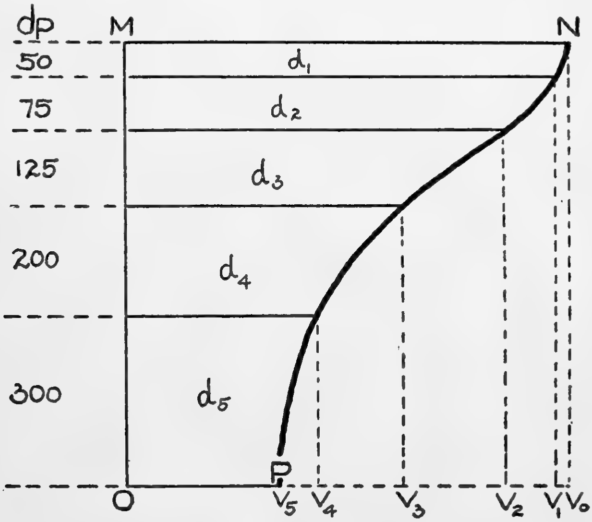

FIG. 9.—A graphic means of illustrating the mathematical integration customarily employed in computing the dynamic depth to a given observed pressure beneath the sea surface

The area MNPO (assumed equal numerically to D_a) is formed partly by the curve NP, which represents varying values of v, and the side MO, which indicates the scale of pressure. The value of D_a, therefore, represented by the area MNPO is equal in value to the sum of all the smaller areas d_1, d_2, d_3, d_4, and d_5. The area d_1 (and the values of all the other small rectangles in similar manner) may, with sufficient accuracy, be put equal to

$$d_1=\left(\frac{v_0+v_1}{2}\right)dp_1$$

or

$$D_a=\left(\frac{v_0+v_1}{2}\right)dp_1+\left(\frac{v_1+v_2}{2}\right)dp_2+\left(\frac{v_2+v_3}{2}\right)dp_3+\left(\frac{v_3+v_4}{2}\right)dp_4+\left(\frac{v_4+v_5}{2}\right)dp_5$$

which equals the value of the gravity potential, relatively to the sea surface, expressed as a depth in dynamic meters at which the pressure

of 750 decibars prevails. Other verticals are computed in a like manner and

$$D_a - D_b = \Delta D,$$

which represents the value of the force tending to produce acceleration of the water particles in the plane of the closed rectangular curve ABDC. The direction in which the force tends to act may be deter-

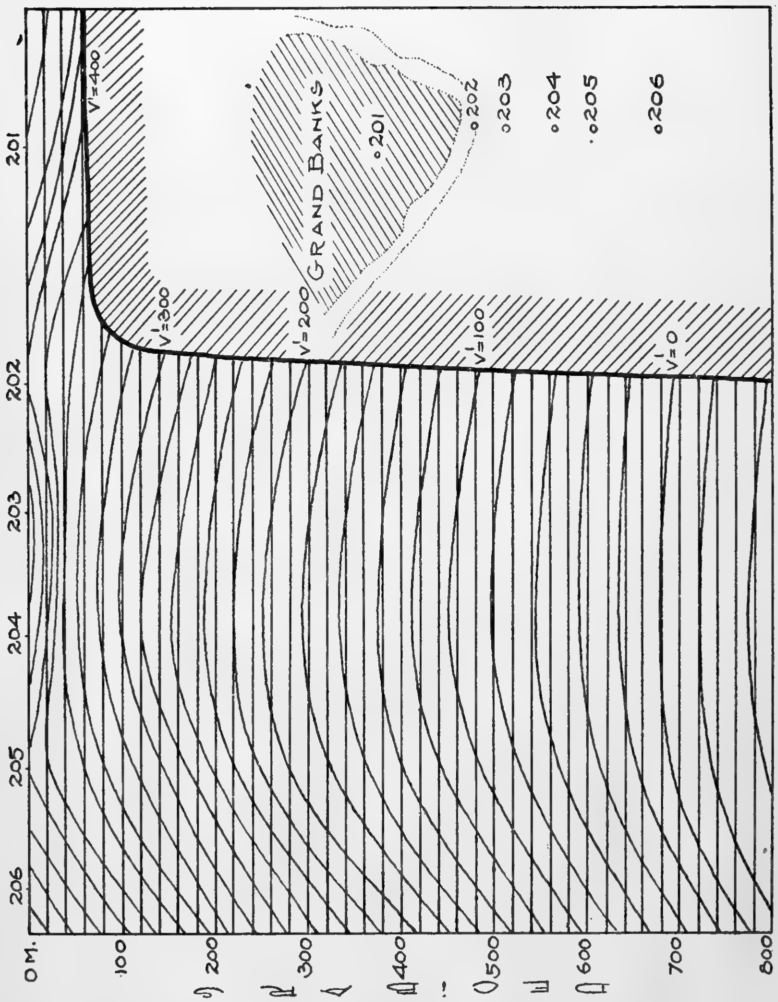

FIG. 10.—Distribution of specific volume in a section south of Newfoundland May 5–7, 1922, and also a cross-sectional view of the solenoidal tubes, each complete parallelogram of which represents the presence of 400 solenoids. Horizontal scale, 1:2,000,000; vertical scale, 1:5,000

mined by the relative values of v, the water being forced upwards most pronouncedly at that vertical where the values of v are a maximum.

It is customary and of assistance in dynamic investigation of an ocean mass to represent the distribution of specific volume, as found by actual observations, graphically in vertical projection, the pressure in decibars being shown as ordinates in the graph. Figure 10 includes a line of stations, 201 to 206, taken from the records of the International Ice Patrol, and furnishes an example of such a method of illustration.

In this particular figure the horizontal lines have been drawn for every 20 decibars. The curved lines represent lines of equal specific volume and are drawn for every 20 units in the fifth decimal place of v. In Figure 10, v^1 means 10^5 $(v-0.97000)$. Since a solenoid is formed by the intersection of isobaric surfaces with isosteric surfaces, it is not difficult to see that a vertical plane, such as illus-

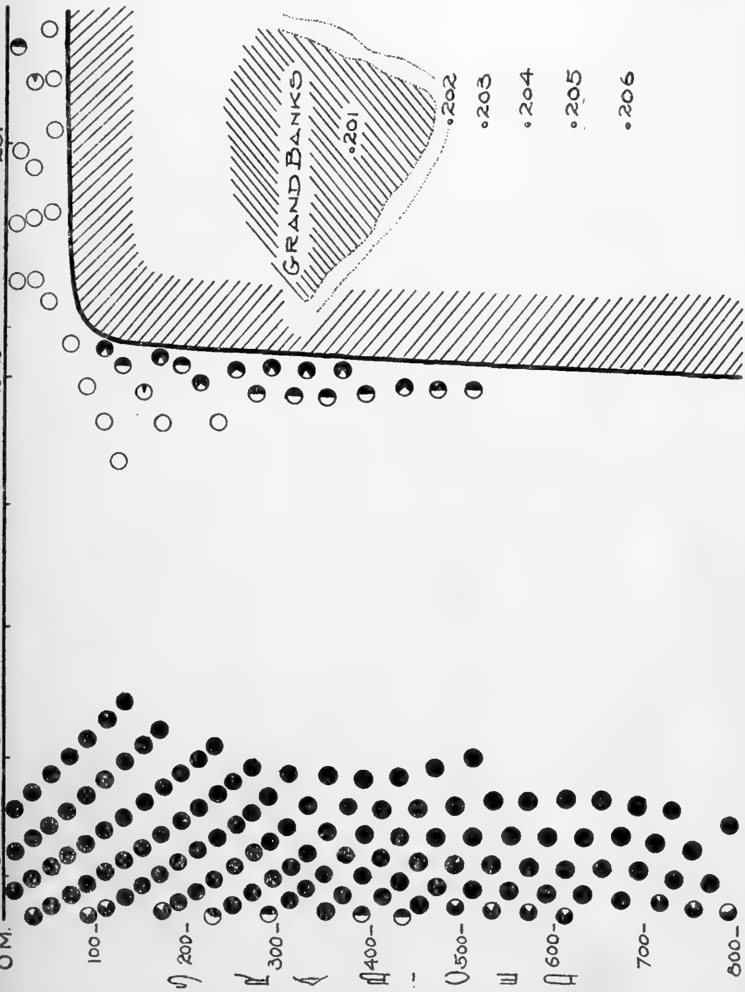

FIG. 11.—An effective illustration of the distribution of solenoids and the dynamic tendencies in a vertical section taken approximately at right angles to both the Gulf Stream and the Labrador Current south of the Grand Banks, May 5-7, 1922. Each whole dot represents 400 solenoids, which gives approximately 50,000 solenoids for the Gulf Stream as represented by the black circles, and about 12,200 solenoids for the Labrador Current as shown by the white circles. The current of the Gulf Stream is represented as flowing perpendicular to the plane of the paper toward the reader and the Labrador Current in the opposite direction. Horizontal scale, 1:2,000,000; vertical scale, 1:5,000

trated in Figure 10, page 26, will intersect the solenoidal tubes forming a number of parallelograms, each one of which indicates the presence of 400 solenoids.

The distribution of forces tending to produce acceleration in such a vertical section may be further emphasized by erasing all the isobaric-isosteric lines after the location of the centers of the parallelograms have been marked out. This method of illustration is shown in Figure 11.

Where the isosteres lie deepest and the inclination is greatest, there is indicated at that place a tendency to push the water upwards with a maximum strength, and where the isosteres lie highest, there the force is at a maximum tending to drive the water downwards. But whatever the position of the isosteres may be, it is well to bear in mind that when the section lies at right angles to the direction of the current, there is no actual movement of the water particles within the vertical plane whatsoever. The value of the solenoids lies in the fact that they express the *presence* of a force or forces tending to cause circulation around the rectangle. The Ferrelian force (effect of earth rotation) precludes *actual* movements restricted solely parallel to the current path AB, Figure 7, page 23, as previously described.

DETERMINATION OF DYNAMIC DEPTH, STATIONS 205 AND 206

We may continue to treat the Ice Patrol records of stations 201 to 206 dynamically, by computing the values of specific volume from the given station data and correcting the same to specific volume in situ; then, by means of the equation on page 25, determine the dynamic depth of the successive isobaric surfaces of observation. In order simply to illustrate the methods customarily employed, we have selected two stations only, stations 205 and 206 located on the northern edge of the Gulf Stream south of Newfoundland. Similar procedure and similar results follow, of course, in like manner from other given station data.

The abbreviations appearing at the top of the columns in the preceding compilation of computations are explained as follows:

Column 1 (dp) represents the difference of pressure in decibars of successive observed depths, which for all practical purposes is equal to the differences in depths of observation in meters.

Column 2 contains the depths at which observations were made.

Column 3 (t) contains the observed temperatures.

Column 4 (s) contains the determined salinity.

Column 5 (d_t) contains the density as found directly from the temperature and the salinity. (Contraction adopted, see p. 2.)

Column 6 (Table III) is a form of inversion table combined with other corrections (see p. 18).

Column 7 (Table IV) contains the combined corrections with due regard to signs for the three factors, pressure with depth, with temperature, and with salinity (see p. 19).

Column 8, contains the values of $(1-v)\ 10^{5}$, where v represents the specific volumes in situ.

Column 9, contains the mean values between the successive depths of observation as they appear in column 8.

Column 10, contains the product of the values as contained in column 9 and the difference of pressure in decibars as shown by column 1.

Column 11 (Σ_2) contains the results obtained by adding progressively the successive ciphers as contained in column 10. Values from columns 6 to 11, inclusive, are negative throughout.

Column 12 (E) contains the calculation of the dynamic depths of the observed isobaric surfaces. Found by combining values in column 2 with those in column 11.

Column 13 $(E-E_1)\ 10^5$ contains the anomaly of the dynamic depth of observation—i. e., it represents the difference in dynamic depth between the isobaric surface actually observed and the position of the same isobaric surface in a sea of 0.0° C. and 35 per mille salinity.

Column 14 (V) 10^5 contains the specific volume in situ, or one minus the value as contained in column 8 multiplied by 10^5.

Column 15 $(V-V_1)\ 10^5$ contains the anomaly of specific volume in situ, or, in other words, the difference in specific volume in situ as found from that at a similar depth in a sea of zero degrees Centrigrade and 35 per mille salinity. The values for the dynamic depth (D_1) and the specific volume in situ, (V_1), as found in an ocean of zero degrees Centigrade and 35 per mille salinity, are given in the following table, Table V. The selected depths recorded therein are the same as those previously carried in Table IV.

TABLE V*

E_1 = dynamic depth in sea 0° C., 35 per mille. V_1 = specific volume in sea 0° C., 35 per mille.

Decibars	E_1	V_1	Decibars	E_1	V_1	Decibars	E_1	V_1	Decibars	E_1	V_1

* The values shown are based upon those contained in Table 8H, Bjerknes' "Dynamic Meteorology and Hydrography," Carnegie Inst. Pub., 1910.

The isosteric lines, Figure 10, page 26, represent in vertical section, the distribution of the specific volume in situ (v). But except in regions where rapid currents prevail, the lines of equal specific volume vary little, especially in the greater depths, from either the lines of equal pressure or the lines of equal depth. This is due to the fact that the effect of the increasing pressures with the depth more than

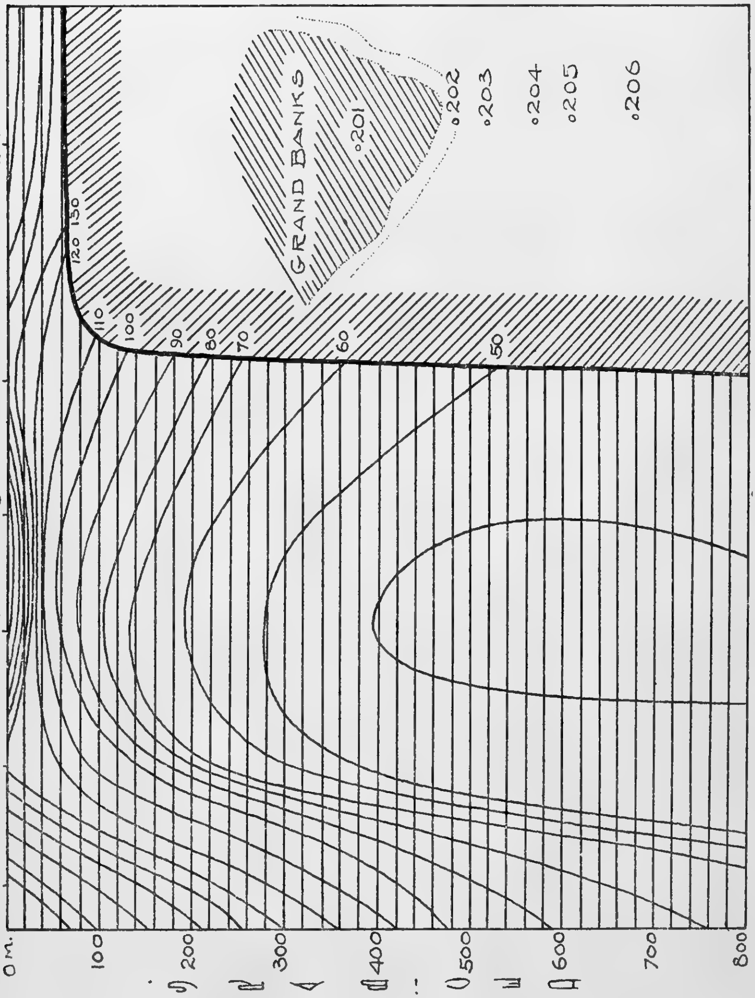

FIG. 12.—A dynamic section constructed from the values of the anomalies of specific volume $(V-V_1)\ 10^5$ at stations 206 to 201. This is an example of the most approved method of illustrating in vertical profile the dynamic conditions found prevailing in a water mass. Horizontal scale, 1: 2,000,000; vertical, 1: 5,000

offset the variations in the specific volume due purely to temperature or salinity variations. In order to secure a more striking graphic representation of the distribution of specific volume in situ, it is customary to draw the isosteres in accordance with the values of $V-V_1$ (see computations, column 15, p. 28). Although these ciphers are of a smaller numerical value than the actual specific volumes, yet they provide a greater contrast than the latter, and a section thus

drawn is the type most commonly employed for purposes of illustration. A dynamic section, Figure 12, formed by stations 201 to 206, International Ice Patrol, 1922, is shown on page 30.

VELOCITY—HOW DETERMINED

We may now return to a consideration of equation (f), page 24, in order to find the velocity of the current between stations 206 and 205, by substituting at the same time for d_a and d_b the values as found at the six levels of observation of the two foregoing stations. Since the velocity is the term desired, equation (f), page 24, may be written in the following form:

$$c_o - c_1 = \frac{(d_a - d_b)\,10^5}{2\omega \sin \phi_m L 10^5} \qquad \text{(g)}$$

where $\phi_m = 41° - 10'$, the mean latitude of stations 206 and 205. The value of 10^5. $2\omega \sin \phi$, by Table VI, page 32, is found to be equal to 9.60. The multiple 10^5 is introduced simply to bring the velocity values into centimeter-gram-second terms. L, which is the distance between stations, is equal to 32 miles, or 59 kilometers. (See Table VII, p. 33.)

Stations	Depth in dynamic meters				
	50	125	250	450	750
205	48. 71750	121. 75713	243. 40776	437. 84276	729. 08476
206	48. 68875	121. 69188	243. 27250	437. 59850	728. 72150
$d_a - d_b$	0. 02875	0. 06525	0. 13526	0. 24426	0. 36326

If we treat the values of $d_a - d_b$ as whole numbers and divide them by the value of $2\omega \sin \phi_m L\ 10^5$, the latter of which is found equal to 569.28, we obtain the following:

	50	225	250	450	750
$C_0 - C_1$	5. 0	11. 5	23. 8	42. 9	63. 6

If it is assumed that c_1 is equal to zero at a depth of 750 decibars (meters), then the following velocities are furnished at the various levels of observation, from the surface downwards. (If it is desired to express velocities in terms of knots per hour, 10 cm./sec. is equal approximately to 0.2 knots per hour.)

Meters or decibars	0	50	125	250	450	750
C_0— in cm./sec	64	59	52	40	21	0
C_0— in Kt./Hr	1. 3	1. 2	1. 0	0. 8	0. 4	0

It is often desirable to express the velocities at the various levels of observation graphically in the form of a current diagram, in which case it is customary to measure the velocity units along the abcissa and the depths along the ordinate. The graphic representation of the current between stations 205 and 206 is shown by Figure 13.

Table VI is a copy of a table (Table 12), which first appeared in a contribution by Sandstrom and Helland-Hansen, in "Report on Norwegian Fishery and Marine Investigations," Volume II, No. 4, Bergen, 1903. It contains the computed values of $2\ \omega \sin \phi\ 10^5$ for each degree of latitude.

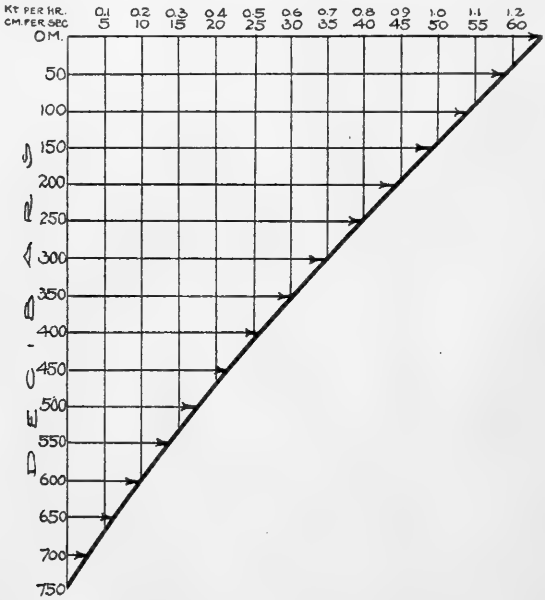

Fig. 13.—Current velocity diagram, northern edge of Gulf Stream between stations 205 and 206, May 5–7, 1922

The velocity values as they are usually finally shown, represented by c_o, page 31, are the differences between the movement on the surface and that at a level where it is believed motionless water lies. But it is important to bear in mind that as a result of dynamic computations, the values of velocities are expressed in terms NORMAL TO THE VERTICAL SECTION which may include any two stations. Another step is necessary if it is desired to obtain the value of the real velocity. Let us assume that the direction of flow but not the rate is known. In Figure 14 suppose the direction of the current is represented by the parallel lines AM and BM_1, between the two stations A and B. Furthermore, let it be given that the velocity normal to the section has been computed by means of equation (g), page 31, and that it is given on the figure as the line K. We now wish to determine the true velocity, V, which lies in a direction parallel to the lines AM and BM_1, and which forms the angle a with the computed velocity. The value of V, it is easy to see from the figure, is equal to $\frac{K}{\cos a}$. The same results may be obtained graphically by laying off the angle a and dropping a perpendicular from the end point of the known side K upon the unknown side V, and then measuring the length of the latter in units the same as K.

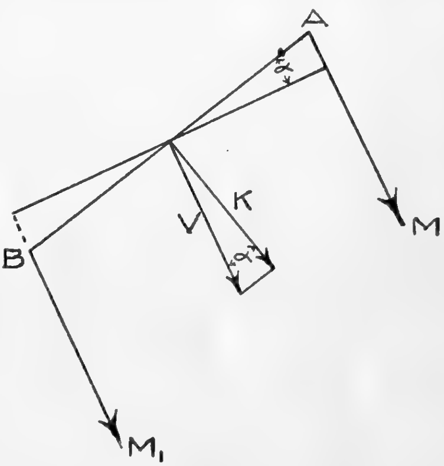

FIG. 14.—Lines AM and BM_1 indicate the known direction of the circulation. K represents the computed velocity normal to the sectional line AB. To find: The true velocity (V) of the current

In Figure 15, AB represents the path of the current; AE, the resultant of the real physical forces; and AC, the quasi force due to earth rotation, acting with the same magnitude but in the opposite direction. The two vectors AE and AC lie in one and the same plane, EAC, which is perpendicular to the course of the current. The fields of forces may be investigated by regarding them graphically in either a vertical view, called a dynamic section (see fig. 12, p. 30) or in a horizontal view called a dynamic topographical chart (see fig. 19, p. 39). Both vertical and horizontal projections, it will be found, assist to reveal particular knowledge regarding the types of forces involved. It will lead also to a clearer understanding of the relative position of the forces, and, moreover, to the course of the current, if we now review some of the fundamental notions pertaining to such representations of forces. The well-known method of regarding a force as represented by equiscalar surfaces and unit scalar sheets is especially applicable here. The potential value of an irregularly formed equiscalar surface, obviously, can be traced by its intersections with a series of unit parallel horizontal planes. The rate of variation of contours (intersections) measured along a normal vector called the gradient is a direct expression of the acceleration of the scalar force. In Figure 16

FIG. 15.—Resolution of the two principal forces in a gradient current AB; AE, the forces due to Archimedean tendencies; AC, the Ferrelian force

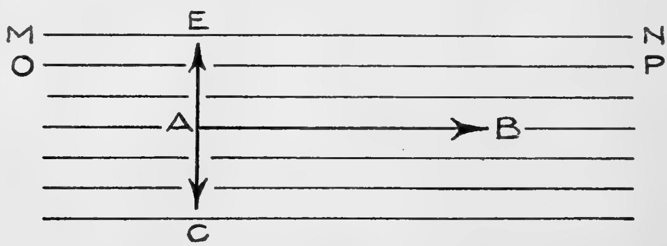

FIG. 16.—A diagram of forces similar to that shown in Fig. 15, but with the addition of dynamic isobaths MN, OP, etc., which show the position of such contours (when friction is disregarded) relative to the actual movement of the water particles

the vector AE representing the acceleration due to primary forces in the sea provoking currents may be regarded as a gradient force due to the variations in level. These variations are in horizontal projection shown by a series of horizontal lines (dynamic isobaths) MN, OP, etc., all perpendicular to line AE, and inscribed on the scalar field of the force. But MN, OP, etc., are also parallel to the line AB, the stream line of the current. Lines MN, OP, etc., then, correspond to the

dynamic contours of a given isobaric surface as illustrated by the dynamic topographical chart described on page 37 (see fig. 19). Therefore it follows that the dynamic isobaths recorded on such charts possess a tremendous significance in as much as they delineate the courses of the water particles over any given area that has been investigated. Not only may the paths of the currents be traced on such charts, but the degree of compactness of the dynamic isobaths along the gradient at right angles to the current, is a measure of the relative velocity of the current. The closer together the contours lie in any given latitude indicates the more rapidly the current is flowing at that time and place.

DIRECTION OF FLOW

The direction toward which the water moves is, of course, requisite information which may be obtained best perhaps by reference to a vertical section—i. e., the dynamic section. If a plane be passed

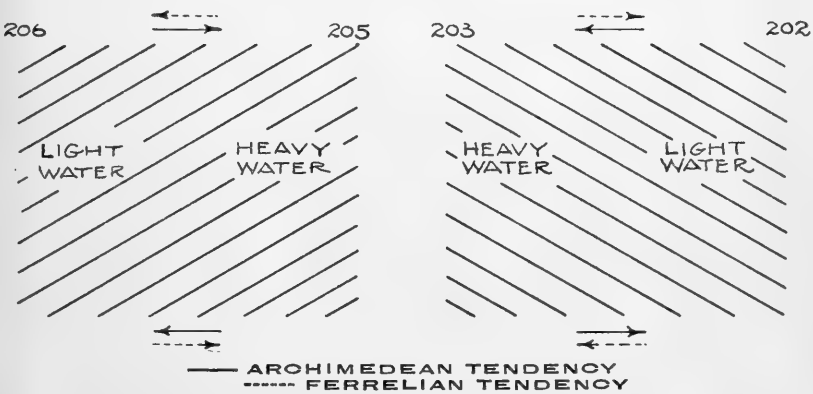

FIG. 17.—Showing the two types of distribution of specific volume in vertical section and the resultant tendency toward flow of the water in consequence

vertically downward through the plane of the forces AC and AE (fig. 16 p. 34) and a distribution of specific volume be secured, a dynamic section similar to Figure 12, page 30, will result. Consideration of the closed curve formed by the two verticals at stations 206 and 205 will reveal the fact that the water being lighter to a greater depth at 206 than at 205 tends to be forced upward at 206 and downward at 205. But when the current is constant there is no actual movement of the water particles in these planes, as the real forces are exactly counterbalanced by the Ferrelian force (effect of earth rotation), the latter of which acts in a direction opposite to the tendency of the Archimedean forces. The real movement of the water particles, as represented by the foregoing figure, takes the form of a current which flows at right angles to the plane of the dynamic section. In such a distribution of forces as shown by Figure 17 the current would run in a direction through the paper, either toward or away from the

eye of the reader. Provided that the water is moving faster in the surface layers than in the depths, the rule follows: Look in the direction toward which the current is running, in the Northern Hemisphere, and the lightest water will always lie on the right hand. The vertical differences of velocity may be calculated from equation (f), see page 24, which is affected fundamentally by the values of temperature, salinity, and depth, at any two verticals in a plane and which it is important to note lies at right angles across the path of flow.

GENERAL SUGGESTIONS FOR A PROGRAM OF HYDROGRAPHICAL SURVEY

Ocean currents, it has been pointed out, may be determined by a distribution of temperature and salinity in a plane, the position of which is perpendicular to the flow of the water. Conversely, if no forces are found as represented by the position of the isosteres and isobars in vertical section, then there is no current at right angles to the plane of the section. It is easy to see, on the other hand, that a section parallel with the course of a current contains no information whatsoever regarding its movement. Hydrographical survey of extensive ocean surfaces involves in any event a large program of time and expense, and the task grows to considerable magnitude, especially when the work devolves upon the efforts of one vessel. An ideal program, of course, includes a maximum number of oceanographic stations distributed netlike over the area to be investigated, and wherein the promulgation of the work most nearly approaches a simultaneousness of observation. Unfortunately, the ideal survey rarely occurs, and it is usual that resort is made to lines of stations along a vessel's track. Under such conditions it is apparent that before commencing the observational work the particular area should be studied carefully with respect to all previous, available knowledge of a hydrographical nature, remembering that the lines of stations in a program of dynamic investigation should run in such a manner that the sections secured approach most nearly to right angles across known or suspected currents. As an example let us take the region around the tail of the Grand Banks where there are two main movements. (1) The Labrador Current is the inshore set, which flows southward along the east side of the Grand Banks and to a variable distance around the "Tail." (2) Offshore in the Atlantic basin the easterly moving masses of the Gulf Stream, guided by the trend of the bottom configuration, progress in a generally opposite direction to the cold water inshore. A program of dynamic investigation in this region should be based upon a series of lines of stations running offshore in a direction normal to the Grand Banks' slopes as shown by Figure 18. Stations should be taken as close together (and repeated as often) as practicable in order that the influence belonging to tem-

porary boundary waves and vortex movements be disassociated from a representative picture of prevailing conditions. (cf. Helland-Hansen and Nansen, "The Norwegian Sea," Bergen, 1909.) To such an end the dynamic features of modern physical oceanography are best carried out by several craft cooperating in one systematic program of investigation, which may or may not extend over great expanses of the ocean. Here is an important requirement which would appear to demand certain revisions in the program of expeditions, which in the past have usually been performed by one vessel sailing under a more or less roving commission. These modern methods in dynamic

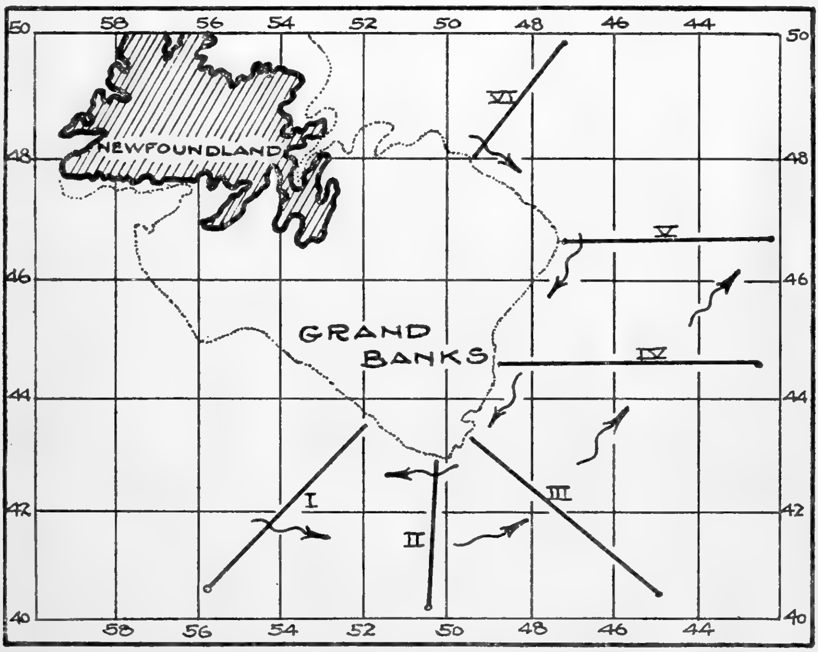

FIG. 18.—A series of station lines radiating from the Grand Banks is an example of the correct methods to employ in order to obtain the best collection of material leading to an investigation of the currents in this region

oceanography, particularly the graphic representation as embodied in the dynamic topographical chart, provide, furthermore, an easy and efficient means of mapping currents over extensive ocean surfaces—advantages which are bound to guarantee a great employment for this science in future hydrographical surveys.

DESCRIPTION OF A DYNAMIC TOPOGRAPHICAL CHART (CURRENT MAP)

We now come to the description of a dynamic topographical chart, a subject which has been reserved until the close of the various methods of illustration, because, from its practical importance, it merits especial emphasis. The basis for the construction of such a projection depends fundamentally on the dynamic computations

previously discussed on page 28. It possesses great practical advantages in that it presents two pertinent, desirable pieces of information, viz, (1) the direction of movement, and (2) the relative rate of flow of the current, over any given area. Let us suppose that the temperature and salinity data, surface to 750 decibars, have been collected from a sufficient number of stations in the region south of the Grand Banks. This, as a matter of fact, corresponds to an actual oceanographical investigation carried out by the International Ice Patrol in these waters during the spring of 1922. Dynamic treatment of these data leads through the accepted methods of calculation as shown on page 28. Column 12 on that page contains the dynamic depths of the successive surfaces of observation, and also the material for the construction of a dynamic topographical chart, of which Figure 19, page 39, is an example.

An isobaric surface, the dynamic topography of which is the subject of interest, may be visualized as spread out beneath the surface of the sea, an undulating floor, the depth of which we plumb with the same reality as the more tangible floor of the ocean is sounded out by the hydrographer. As a first step toward the mapping of currents, let us investigate any one of the standard isobaric planes of observation adopted by the International Ice Patrol, viz, 50, 125, 250, 450, and 750 decibars, by plotting its dynamic soundings on a map at those positions in latitude and longitude where the respective stations have been located. This procedure, it is plainly seen, is identical to that in which depths to the bottom are fixed on any ordinary navigational chart. If, as a next step, equipotential (level) planes are passed at frequent heights through the selected isobaric surface which is under investigation, a number of lines of intersection are formed, which for convenience may be called dynamic isobaths. If now we recall the fact that when the accelerating force of friction is disregarded the movement of water particles on an isobaric surface tends along such a surface, as well as along the same equipotential surface (see p. 34, fig. 16), it is not difficult to appreciate the significance of dynamic isobaths. The small sketch in the lower left-hand corner of Figure 19, page 39, shows a series of dynamic isobaths and the direction of the two forces which are always present wherever there prevails translatory movements of water particles in a steady current. Friction, for all practical purposes, may be disregarded. (See p. 43). (1) AE illustrates the resultant of the forces which impel and maintain gradient flow; (2) AC represents the Ferrelian force acting in a plane 90° to the right of the current; and (3) AB is the path of the actual established movement following along the dynamic isobaths. When these latter are recorded on an ordinary geographical map, as a series of dynamic contours, it permits the reader, at a glance, to picture the course followed by a water particle throughout the region which is under survey. Figure 19 is shown as an example of a dynamic

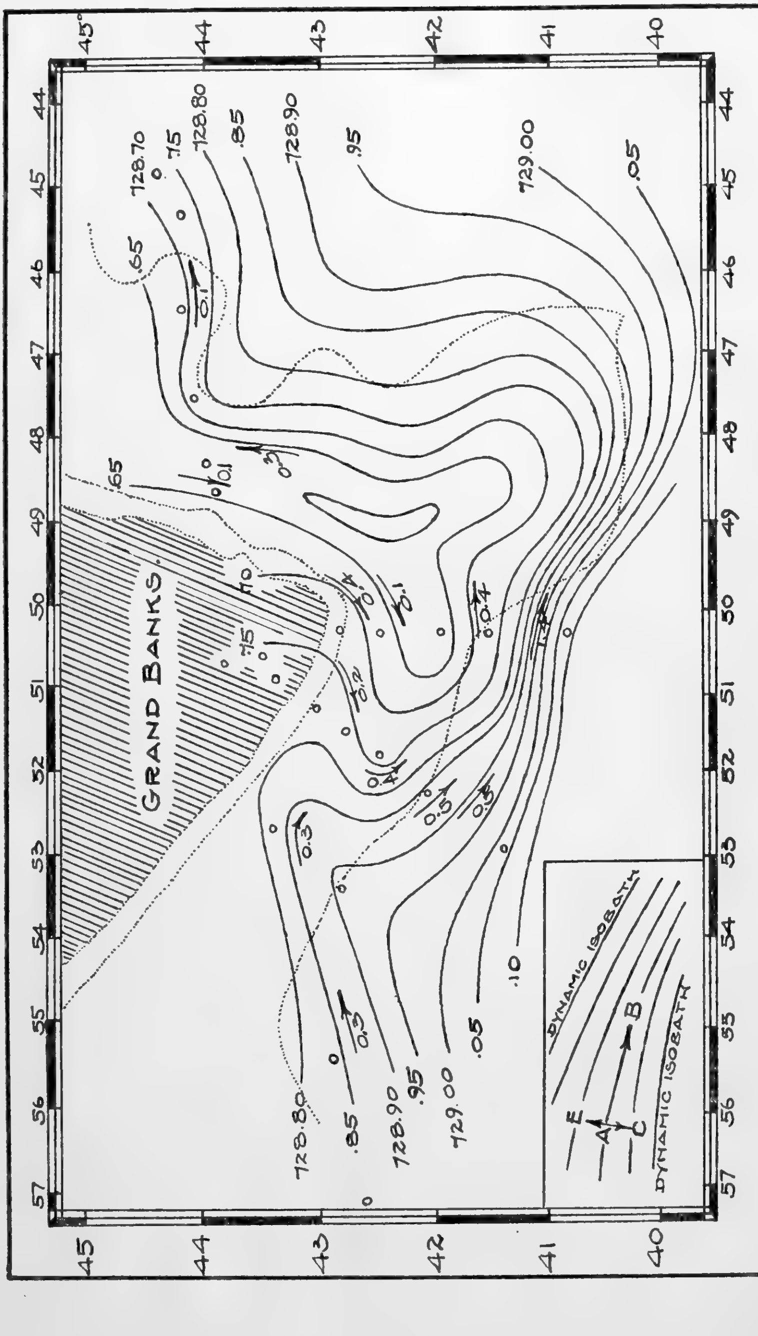

FIG. 19.—An example of a dynamic topographical chart (an ocean current map)

It is interesting to observe that the easterly position of cyclone track B on Figure 6, was due without much doubt to the presence of the aforementioned anticyclone. Weather bulletins were received May 5, 6, and 7, containing information that a depression was forming in the region of Bermuda, but due to the lack of ship reports it was impossible to ascertain definitely the movement of the center. During the night of May 8 our barometer began to fall. which from past experience indicated the approach of a storm within a radius of about 500 miles. The next morning upon constructing the weather map the center was revealed near Port aux Basque; it probably had followed a northerly path from Bermuda as indicated on Figure 6. During the next few days the weather maps indicated a tendency of

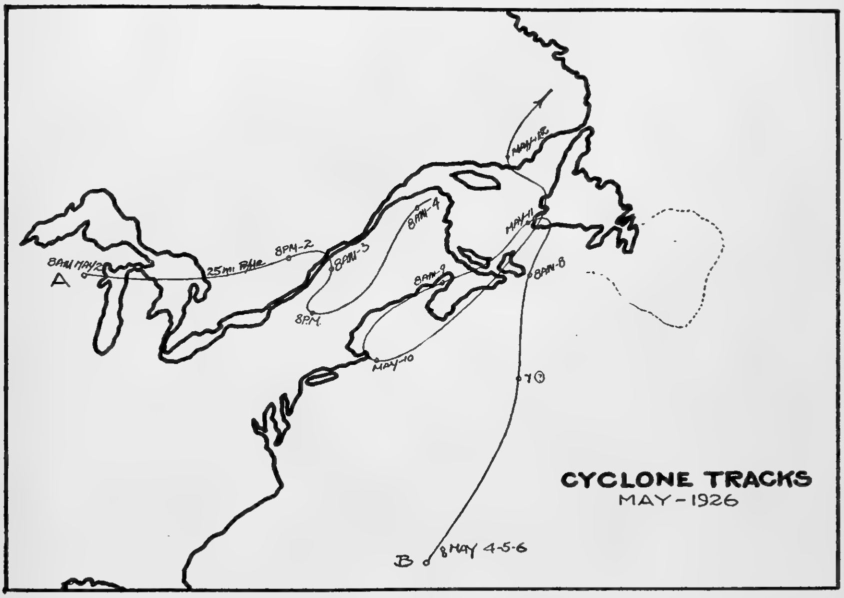

Fig. 6.—May cyclone tracks

the pressure to remain relatively low to the westward, depression centers being recorded from Nantucket to Sydney. On May 11 a deep center appeared near Sydney and moved in a path across the Gulf of St. Lawrence and out to sea. The effects of this distribution set up an indraft of southeasterly winds consisting of warm moisture-laden air pulled across the ice regions from out in the Atlantic. This condition incidently produced the longest period of fog which we experienced for the season.

The two weeks from the 13th to the 27th marked a change in the previously noted tendency of the cyclones to travel consistently along northeasterly tracks Where prior to this period individual centers moved rapidly across the country we now saw several small vortices (families) following meandering paths as if they were the

prey to several factors no one of which exerted outstanding control. For example, on May 13 a slight shallow depression moved from Illinois eastward to the Potomac and the next day spread into a spacious depression with two centers. One traveled eastward while the other remained stationary until two days later it coalesced with a third depression which had been drifting slowly eastward from the Great Lakes. Contemporary with this modification in the weather we noticed that the wind velocities in general had gradually become less than they had been earlier in the season.

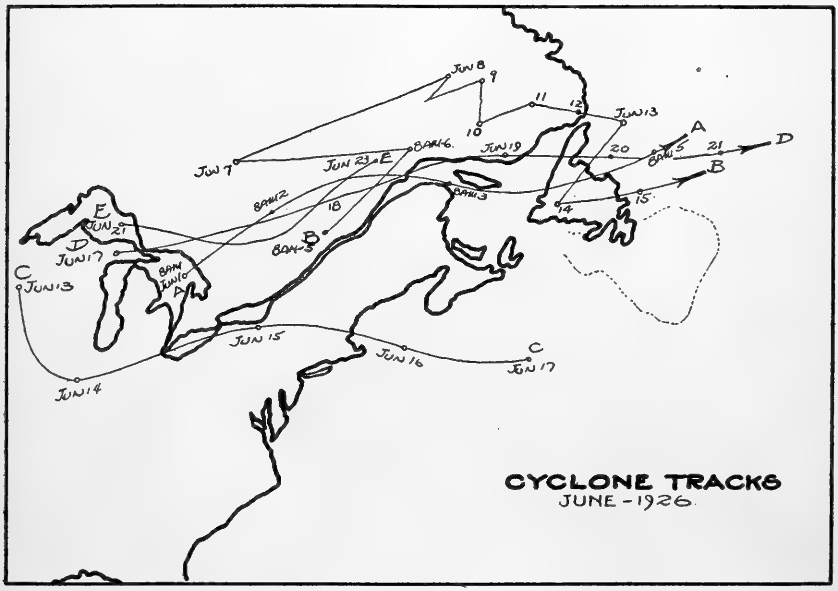

FIG. 7.—June cyclone tracks

May 25 to 30 an anticyclone of vast proportions expanded from the region of central Canada and spread over the entire eastern half of the United States and extended out to include the ice regions. It finally divided into two centers and soon afterward disintegrated completely. It is interesting to examine the flatness of the barograph curve and the presence of clear weather, both of which are recorded on Figure 3, page 35.

JUNE

The most important lesson contained in the cyclone tracks for June (fig. 7) is obtained by comparing the position of the average with the position of the average for the months of March and April. It is clearly indicated that a migration to the northward of the mean cyclone track took place in the course of two months. It is estimated as approximately 150 miles. The explanation for track C, Figure 7,

Gulf Stream, and is well illustrated by the velocity diagram (fig. 13, p. 32). In "B," Figure 20, the velocity of "a" being greater than adjacent particles, or adjacent sheets above and below, is thereby retarded and friction acts to hinder the translatory progress of particle "a." In "C," the velocity of particle "a" is less than either of its immediate neighbors, above or below, and friction therefore

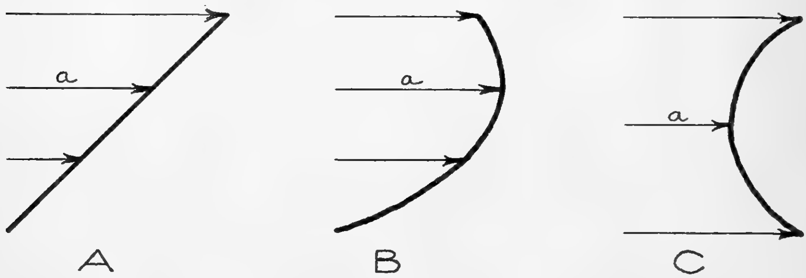

FIG. 20.—Three general types of current velocity diagrams

tends to accelerate the velocity of "a." If the water particles in a current be retarded by a constant accelerating force of friction throughout the depth, then the velocity diagram will assume the form of a parabola.

Cases as shown in "B" and "C" (fig. 20) may also be illustrated by components and force diagrams in horizontal projection as follows:

The dotted lines in Figure 21 represent the direction of flow of the current, and the solid lines are equipotential lines inscribed on the scalar field of the force tending to produce a movement in the sea.

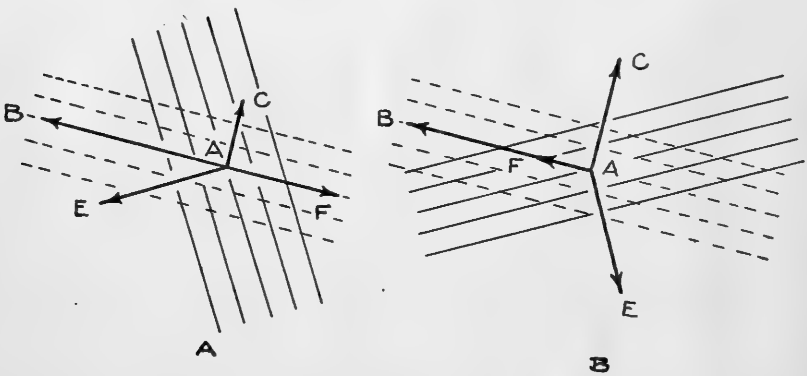

FIG. 21.—The two types of force diagrams belonging to gradient currents when friction is included either as (1) a retarding or as (2) an accelerating force

The gradient AE being perpendicular, of course, represents the force due to variations in gravity potential. AC is the force due to terrestial rotation lying 90° to the right of the direction of the current. By vector analysis we may find the force AF due to friction, where in "A" it retards the current AB, and in "B" it accelerates the same. If all but one of the parallel lines of flow and all but one of the parallel

equipotential projections be removed, the angle between these two may be more easily seen and designated as α, in the figure. It follows that:

$$AF = AC \tan\alpha = 2\omega \sin \varphi V \tan \alpha \qquad \text{(h)}$$

It is seen from this that the force due to virtual friction varies directly as the tangent of α and the velocity of the current. There is, however, very little data bearing on the value of this angle α for various currents at different places and under different conditions. In order to determine various values of α (contemplating of course that there are several assumptions), simultaneous observations should be made regarding the direction and the rate of flow of the current with the aid of current meters, and at the same time observations for temperature and salinity should be taken in a section at right angles

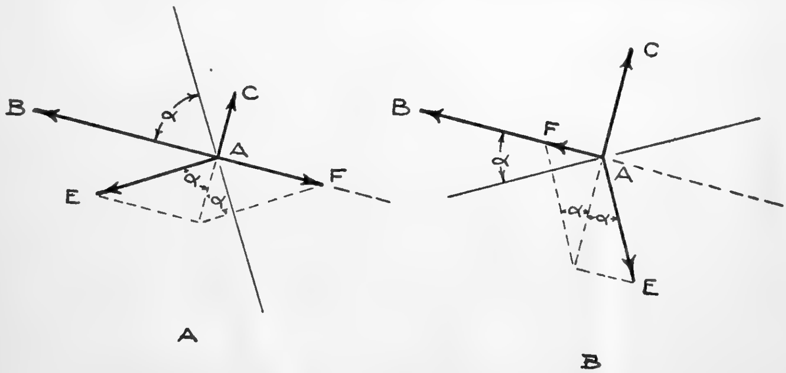

FIG. 22.—An illustration similar to Fig. 21, but with all but one of the dynamic isobaths erased and all but one of the parallel lines of flow erased

across the current. By such a means the virtual friction, as represented by the line AF, can be tabulated directly. The value of this effect, however, as it enters the present discussion, may be safely stated, rarely exceeds a magnitude of 0.05 to 0.07 knots per hour, either to accelerate or to retard the flow of a steady current, and such ciphers being relatively insignificant can be disregarded in the practical determination of currents.

EFFECT OF BOTTOM CONFIGURATION ON CURRENTS

Frictional retardation attains considerable proportions, however, between flowing water particles in contact with the fixed configurations of an ocean basin. Ekman has suggested as a result of mathematical investigations that if an ocean current proceeding along in a steady manner moves in over a gradually shallowing shelf, it will tend to be deflected more and more to the right in the Northern Hemisphere. On the other hand, if by a continuance the bottom begins to recede deeper and deeper from the surface, then the current will be proportionately deflected to the left. This phenomenon

is revealed by reference to certain current charts (dynamic topography) of which the Ice Patrol has record. As an example, we might call attention to Figure 19, page 39, wherein the position of the Gulf Stream relative to the 4,000-meter contour, clearly indicates that the current flooded in up the grade occasioned by the southeasterly extension of the Grand Banks (about 53° west longitude), but meeting increased resistance in the constantly shallowing depths it was deflected to the right, offshore. The current, proceeding along in this new direction where the depths increase, tended to swing to the left, inshore; and so in this fashion its course may be traced as it flowed along the continental slope in a serpentine path.

Inshore, over continental shelves, it has been found that the coastal waters are in a slow primary circulation which Huntsman believes due to the pumping action of the tides combined with the effect of terrestial rotation. It has been expressed in a general statement, viz, bottom configuration in the Northern Hemisphere tends to deflect currents to the right (cum sole), around islands and shoals, and to the left (contra solem), around basins and deeps.

TIDES

One of the external forces provoking currents in the sea was ascribed to the tides (see p. 1). Such currents rotate in their movement either clockwise or counterclockwise one complete cycle, when unaffected by other influences, in a period of 12.4 hours. The theory of semidiurnal tides is based upon a series of waves which are known sometimes to be propagated great distances, but the discussion of the form of such waves, and the theory of orbital motion given to the water particles, is too lengthy to be included in this paper. Those interested in a more detailed exposition are referred to Darwin (cf. Tides and their Kindred Phenomena in the Solar System.) We may remark, however, a few generalities regarding the various tidal phenomena as they affect certain oceanographical problems. Tidal currents in the deep ocean basins are of comparatively subordinate importance, but near continental slopes and over shelves they may attain great magnitude. Even when such slopes and shelves extend far out into an ocean basin, tidal effects remain quite prominent. The sheet of water lying over the Grand Banks, for example, averaging a thickness of about 35 fathoms (65 meters), receives a regular tidal clockwise rotation which attains velocities ranging from 0.2 to 0.5 knots per hour. Well-marked rippling on the surface during periods of calm sea, moreover, has been observed along the eastern edge of the Grand Banks, which it is easy to believe were caused by the semidiurnal tidal wave meeting the rise as presented by the eastern face of the bank. Icebergs around the Grand Banks have often been carried inshore and grounded temporarily during calm weather when no other cause seemed so plausible as that of a favorable tidal set at the time and place.

Various places, as a result of land and shoal formations, may be under the influence of two tidal waves in varying phases. If these latter are similar and both at a maximum, then follows a maximum range of level and a minimum velocity of current. On the other hand, where two tidal waves meet in opposite phases, a minimum range of level results but a maximum strength of current is attained. Tidal currents on soundings are usually determined by the aid of current meters, which in the open sea are often illustrated by an elliptical form of diagram when the current is purely tidal. The water over shelves and near continental slopes is usually in progressive movement as well as being under a tidal influence, and in those cases the current diagram will be a resultant of the two different types of movement. Another method of illustration of current observations is that of a number of vectors radiating from a common center and where the position and relative length of the successive vectors indicates the direction and velocity respectively of the current reckoned in moon hours.

VARIATIONS IN ATMOSPHERIC PRESSURE

Among the causes of currents ascribed to external forces, there was included (see p. 1) that of the atmosphere as it pressed down upon a sea surface unequally. Some very interesting observations have been collected which deal with this subject where the bodies of water are partially inclosed by basins and the currents thus produced are forced. An example of such geographical qualifications is illustrated by the Mediterranean Sea and its connection—the Strait of Gibraltar—with the Atlantic. Knudsen has found that atmospheric pressure differences between the Baltic and the North Sea can be traced in the acceleration (or retardation) of the current through the Belts and Öresund. Since a difference in atmospheric pressure of 1 centimeter of mercury is equal to about 13 centimeters of sea water, it is not difficult to appreciate that the volume of a water mass which has this dimension as a thickness and an area equal to the Baltic will cause a considerable current when forced through such an opening as Öresund. Apparent natural difficulties have prevented the collection of scientific observations which will throw light upon the degree of this influence in the open sea. Because of (*a*) the absence of boundary surfaces against which the variations in atmospheric pressure may react; (*b*) the compensating effect which results from the progressive movement of such maxima and minima areas over the sea's surface; and (*c*) a counteracting drift current which tends to flow as a result of the accompanying system of winds make it safe to state that in general the relative importance of variations in atmospheric pressure causing currents in the open sea is small indeed. This phenomenon can be totally disregarded in hydrodynamic computations of the ocean.

WINDS

The discussion of the most important of all forces classified as external and provoking currents in the sea—the winds—has been reserved until the last. Winds, as they are treated in this connection, are divided into two groups: (*a*) Those winds the effects from which impel the surface layers—propagate frictionally downward—and produce a drift current only; and (*b*) those winds which by virtue of (*a*) drive water particles against boundary surfaces in the sea and give rise to gradient currents.

Let us first examine (*a*) the current caused by the wind and the earth's rotation alone. Nansen, on board the *Fram* while held fast in the Arctic pack, observed that the drift of his ship was 20° to 40° to the right of the direction of the wind. More recently Ekman has made some very interesting theoretical investigations regarding a wind blowing tangentially over a water surface, taking the rotation of the earth into account. (See Ekman's "Earth Rotation and Ocean Currents," Arkiv för Matematik, Astronomi, och Fysik, Band II, No. 11, Uppsala, 1905.) To begin with, Ekman has made the following assumptions:

1. The ocean be unlimited in a horizontal direction.
2. The depth to the bottom be great.
3. The water mass be homogeneous.

The following deductions are then made:

(*a*) The surface water particles are driven 45° cum sole (to the right in the Northern Hemisphere) of the direction of the wind.

(*b*) This effect is propagated frictionally downward. The direction of the current will alter cum sole in direct ratio to the increase in depth, and the velocities will decrease in geometrical progression.

(*c*) At a certain variable depth, called the frictional depth (or depth of wind current), the water will flow in a direction exactly opposite to that of the surface current, but its velocity will be only about one-twenty-third of that on the surface.

In order to obtain a clearer conception of the penetration of wind currents in the upper levels of an ocean, relative values of c (the velocity of the drift current throughout the vertical range of frictional depth) and D (the frictional depth) may easily be calculated by means of Ekman's formulæ and placed in table form:

TABLE VIII

Direction			Velocity
Meters	α^*	α'	C
0	0	0	C_0
0.2 D	$0.2\,\pi$	36°	$0.53\,C_0$
0.4 D	$0.4\,\pi$	72°	$0.28\,C_0$
0.6 D	$0.6\,\pi$	108°	$0.15\,C_0$
0.8 D	$0.8\,\pi$	144°	$0.08\,C_0$
D	π	180°	$0.04\,C_0$

(*the direction of the wind current at the very surface is assumed to be 45° to the right of the wind). Angles a and a' are the differences between the direction of the surface current and that prevailing at the given fractions of the frictional depth. The same results were first shown graphically by Ekman in the form of a diagram, a copy of which is shown herewith. As an example of the use of Table VIII, and as further illustrated by Figure 23, if the frictional depth be 50 meters, then at a depth of 10 meters the water particles will flow in a direction 36° to the right of the current on the surface. So it is seen that if the surface velocity and the frictional depth be known, the velocity and the direction of the pure drift current throughout the vertical range may be determined. Ekman has found that for practical purposes the equation may be simplified to

$$D=\frac{7.6\,W}{\sqrt{\sin\phi}} \text{- - - - - - - - - (j)}$$

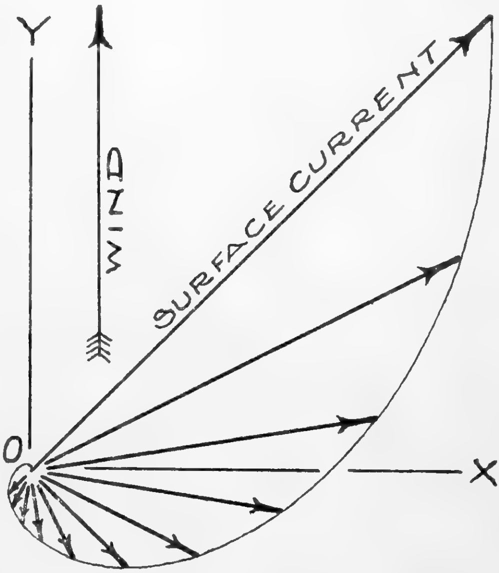

Fig. 23.—Ekman's diagram in which the position and length relatively of the successive arrows represent the direction and velocity, respectively, of the pure drift current, down to the frictional depth, set up as a result of wind and earth rotation alone

(j) is based upon the value of q equal to 1.025; and W represents the wind velocity in meters per second. It is easy to see from (j) that the greater the wind velocity the deeper downward in an ocean will its effect penetrate. Also since sin ϕ is zero at the Equator and 1 at the pole, it follows that given winds will exert a maximum influence at the Equator and the least effect at the pole. The density of the water is of some importance; a given wind current will be stronger and penetrate to a greater depth in a region of light water than in a region of heavy water. Table IX gives

TABLE IX

Wind velocity		Latitude										
Cm. sec.	Beaufort	1°	5°	10°	20°	30°	40°	50°	60°	70°	80°	90°
5	3	238	129	91	65	54	47	43	41	39	38	38
10	5	575	257	182	130	107	95	87	82	78	77	76
15	7	863	386	274	195	161	142	130	123	118	115	114
20	8	1,151	515	367	260	215	190	174	163	157	153	152

the frictional depth for different wind velocities at different latitudes and is computed by means of equation (j). The table is also based upon several assumptions, two important ones of which are, (1) the water mass be homogeneous, and (2) the depth to the bottom be great compared with the frictional depth. Such restrictions, as a matter of fact, differ from conditions actually met in the ocean, but the table gives an idea, nevertheless, of the depth of the pure wind current in the open sea, bearing in mind that when great variations in the density are found, the frictional depths will be less. At such places where abrupt transitions in the density of a water column takes place (e. g., a well-pronounced condition during the summer when the superficial layers become relatively light), then the boundary between the surface water and the heavier underlying mass acts as a virtual bottom in determining the development of the pure wind current. The density curves for the Grand Banks column, for example, often reveal an abrupt transition at a depth of about 20 to 30 meters, and such a discontinuity layer probably indicates the lower limit of the drift current at the time. If the depth of the upper layer be less than the frictional depth, as found by Table IX, then the effect of earth rotation is small and the direction of the wind current will more or less parallel the direction of the wind. On the other hand, at those places where homogeneous water is found extended downward 200 or 300 meters (e. g., in an ocean which has been subjected to the effect of an entire winter's cooling), then we may expect wind currents (after a day or so outside of the Tropics) to develop in characteristic form. (See fig. 23. p. 47.)

A distinction has been made between (*a*) the direct frictional effect of the wind blowing over a surface in the deep open sea, as it sets in motion a pure wind current, and (*b*) a similar effect of the wind but under the influence of coast lines or other hinderances, by which the water becomes amassed against (or sucked out from) such boundary surfaces in the sea. Winds classified as (*b*) bring to the problem a consideration of two subsequent movements known as "the mid-water current" and the "bottom current." The bottom current compensation for the surface current as the latter flows toward (or away from) boundaries. As an example of the building up ability of far reaching currents by a system of prevailing winds, we might regard the northwestern North Atlantic region along the North American coast, stretching from Baffin Land to the southern reaches of Newfoundland. Normal atmospheric distribution, especially well marked in this region during the December–March period, furnishes a strong northwesterly wind component, which a glance at the map will show lies approximately parallel to the coastal trend, Baffin Bay to Cape Race. Ekman has pointed out (see "Earth Rotation and Ocean Currents," Arkiv för Matematik, Astronomi och

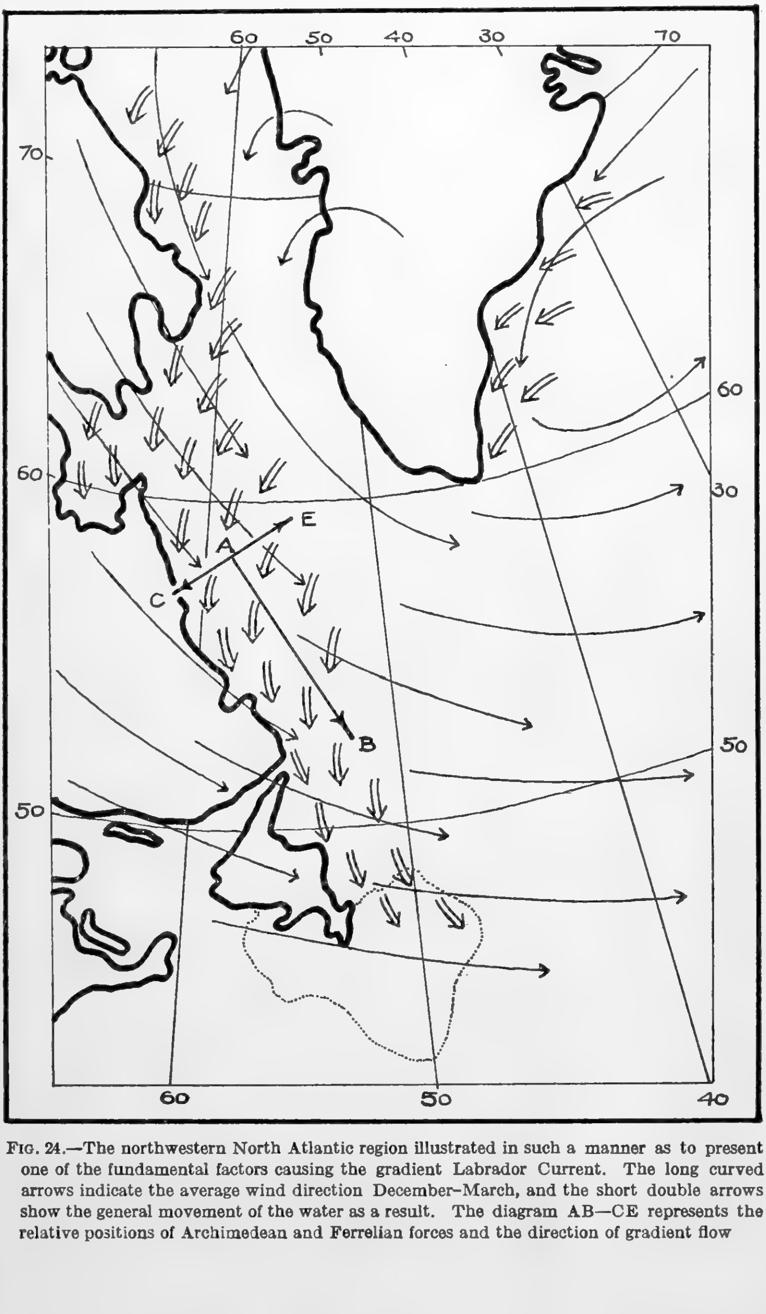

FIG. 24.—The northwestern North Atlantic region illustrated in such a manner as to present one of the fundamental factors causing the gradient Labrador Current. The long curved arrows indicate the average wind direction December–March, and the short double arrows show the general movement of the water as a result. The diagram AB—CE represents the relative positions of Archimedean and Ferrelian forces and the direction of gradient flow

Fysik, Band II, No. 11, Uppsala, 1905) that the influence of a coast line upon currents set up by the wind is to produce a general movement of the water along in the direction of the coastal trend. The bulk of the current—i. e., the mid-water current—flows more or less parallel to the coast line, but as we approach the shore the mid-water current disappears and the surface and bottom systems merge into one with a consequent loss of character. This last-mentioned movement also tends to flow parallel to the shore line. A wind of given strength will produce a maximum effect, states Ekman, when directed 13° to the left of the coast line, which conditions, it is interesting to note, accord closely with relative directions of winter wind and coast line in the northwestern North Atlantic region. Figure 24, page 49, illustrates this particular phenomenon. The long curved arrows represent the average direction of the wind during the December–March period, and the short double arrows indicate the general movement of the surface layers. Offshore, where the depth to the bottom is relatively great, the wind current at the surface will be deflected nearly 45° to the right of the wind, and the mean transport of the water layer of the wind current will most nearly approach a direction 90° to the right of the wind. As we near the shore and shallow water the direction of the wind and movement of the surface water tend to become parallel. The gradient current, which is the most voluminous of the movements, arises whenever the sea surface, which has been deformed into a state of obliquity by the wind, tends to return to the level. A regular state of motion is soon established with a steady flow perpendicular to the pressure gradient, and we are permitted to draw a diagram showing the position of impelling and Ferrelian forces, AE and AC, respectively, with resultant direction of the gradient current as line AB. The time required for such a development must be calculated in weeks or months depending upon the magnitude of the wind and the width of the current. Gradient currents are more or less independent of slight variations in the winds such as affect surface currents, but it is quite probable that variations in the circulation of the atmosphere are followed by corresponding variations in the gradient currents. As an example of such a phenomenon as described in the foregoing we point to the Labrador Current, which may be due to the melting of polar ice, but which, nevertheless, is controlled to a great degree by a system of seasonal winds, December–March, tending to aid the transport of cold water and ice out of the Arctic along the western side of the North Atlantic basin.

TABLE OF CONTENTS

FOREWORD

The London Convention of 1914, the recommendation of which paved the way for the United States to undertake the direct operation of a patrol of the ice regions of the North Atlantic, also went on record in favor of a scientific program and the publication annually of a report of the patrol work. In accordance with the latter feature a bulletin has been published after the expiration of each one of the patrols since 1913.[1] The bulletin herewith follows the customary arrangement of the subject matter of those appearing in former years. First comes the general program and statement of policies which have in the past 13 years become pretty well established. Then follows a narrative of the events which occurred during a total of the seven cruises that made up the patrol for 1926. A brief account is given of the radio operations for the season, a subject which obviously is a vital one when estimating the patrol's efficiency. The oceanographic work this season was featured by the application of new and progressive methods[2] to map the currents in the so-called critical area around the Tail of the Grand Banks.

THE INTERNATIONAL ICE PATROL

1926

The International Ice Patrol for the season of 1926 was carried on by the United States Coast Guard cutters *Tampa* and *Modoc;* the former was in command of Commander H. G. Fisher, and the latter was in command of Commander H. H. Wolf. The Coast Guard cutter *Mojave* was designated as the stand-by vessel. Lieut. Commander Edward H. Smith, was detailed to assist and advise the commanding officers while on patrol.

As in former years the object of the patrol was to locate by scouting, and radio information, the icebergs and ice fields nearest to and menacing the North Atlantic lane routes. In doing this it was necessary to determine the southerly, easterly, and westerly limits of the ice and to keep in touch with it as it moved southward. Radio broadcasts were sent out twice daily giving the whereabouts of this ice and particularly that which was in the immediate vicinity of the North Atlantic lane routes. In order that an intelligent service of the highest degree be rendered to shipping, an oceanographic program was laid down the results of which, it was hoped, would furnish the vessel on patrol with a practical up-to-date current map of the critical, infested ice area under surveillance. The oceanographic work being supportative and secondary in importance was so arranged that it would not hamper the patrol in its primary duty of ice scouting.

A scientific program from which conclusions of practical value may be drawn is an established policy of the ice patrol. The work carried out in 1926 progressed along two general lines:

(*a*) Sonic depth recorder experimentation. The ice patrol was equipped with one sonic depth recorder in 1925 in order that experimental tests be carried out which might lead to the design of a practical device for determining the proximity of bergs not visible because of fog, snow, or darkness. It was found impossible to continue with this phase of the sonic work in 1926, but about 450 hydrographical soundings were taken in order that an accurate and authenic map of the ice regions around the Grand Banks may ultimately result. (See pp. 49 to 52.)

(*b*) Oceanographic work: If the patrol had knowledge of the drift tracks which bergs would follow after arrival at the Tail of the Grand

Banks, more valuable information could be furnished approaching vessels, especially during the protracted periods when fog enshrouds the cold-water regions. Since nearly all the bergs at this gateway to the Atlantic are controlled by a relatively deep-seated circulation, a current map of the critical area where the Labrador current and the Gulf Stream meet, is an indicator of the courses menacing bergs will follow. A practical means of determining oceanic circulation in critical areas was instituted for the first time with the season of 1926. (See pp. 108 to 117.) The methods of this work [1] are set forth in a pamphlet recently published by the Coast Guard.

After the ice was located the patrol began transmitting four daily radio broadcasts, giving ice information for the benefit of shipping, each broadcast being repeated once with an interval of two minutes between the messages. The times at which these broadcasts were sent and also the wave lengths used are given below:

Greenwich civil time	Time seventy-fifth meridian	Wave length	Frequency
		Meters	*Kilocycles*
0000	1900	1,713	175
1100	0600	706	425
1200	0700	1,713	175
2300	1800	706	425

In addition to this service ice information was given to any ship that made inquiry and in cases where vessels were standing dangerously close to ice, the patrol sent them a special message.

The ice patrol in transmitting routine dispatches to Washington operated under the following schedule which had been arranged before the ships sailed from port. After getting the "XA" set in working order a slightly modified schedule superseded the one here. (See p. 16.)

Greenwich civil time	Time, seventy-fifth meridian	
1300	0800	Ice patrol transmits Weather Bureau report to Bar Harbor on 175 kilocycles (1,713 meters), using the "no answer" method.
1700	1200	Washington transmits "no answer" method acknowledgement for 0800 schedule on 113 kilocycles (2,650 meters).
1800	1300	Ice patrol receipts by "no answer" method to Bar Harbor receipt for Washington's 1200 schedule. Use 175 kilocycles (1,713 meters).
0100	2000	Ice patrol transmits "no answer" method to Bar Harbor on 175 kilocycles (1,713 meters), dispatch for Weather Bureau and Hydrographic Office.
0300	2200	Washington transmits "no answer" method acknowledgement for 2200 schedule on 113 kilocycles (2,650 meters).
0330	2230	Washington transmits "no answer" method, a weather forecast for the ice patrol, 113 kilocycles (2,650 meters).
0400	2300	Ice patrol receipts by "no answer" method to Bar Harbor for Washington's 2230 and 2300 schedules.

[1] Smith, Edward H.: "A Practical Method of Determining Ocean Currents." U. S. Treas. Dept. Bull. No. 14.

A more detailed account of the radio activities for the season of 1926 are contained in the section devoted to radio communications, page 14.

A full and detailed description of the behavior of icebergs in the currents in 1926, together with illustrated sketches is contained on pages 53 to 77.

The principal features of the ice patrol season of 1926 have been taken from the detailed reports covering the seven cruises that were made, and this narration forms the first section of this bulletin.

The detailed discussion of the weather, ice observation, results of sonic sounding work, and the oceanography have been grouped together in sections that follow consecutively throughout the bulletin.

32036—27——2

CRUISE REPORTS

THE FIRST CRUISE, "TAMPA," MARCH 25 TO APRIL 11, 1926

In accordance with headquarters telegram the *Tampa* sailed from Boston at 11.55 on the morning of March 25, 1926, and stood out to sea setting a course from the harbor entrance for the Tail of the Grand Banks. Thus was inaugurated the season of 1926. On the second day out we received the first steamer's report of icebergs which referred to a group of seven located on the eastern part of the Grand Bank between latitudes 45° and 43° 30′. This same information was contained in the radio broadcast from Arlington and so it was thought to be the real reason for dispatching the first of the patrol ships to the ice regions.

Sunday, which was our fourth day out, found us about 200 miles west of the Tail of the Grand Banks and there we stopped for an hour to take the first oceanographic station of the year (No. 554), and especially to give new members of the *Tampa's* crew an opportunity during good weather and daylight, to see the manner in which the station work is performed. In the afternoon dispatches were addressed to the wireless officer, Halifax, Nova Scotia, officer in charge compass station, Cape Race; commercial radio station, Cape Race; and the French radio station at St. Pierre, informing them all that the ice patrol ship had now arrived in the ice regions and the same service as rendered to shipping in previous years would be carried out.

Early in the morning of March 29 we arrived at the position of oceanographic station No. 555, located about 75 miles off shore of the southwestern edge of the Grand Banks. It was blowing with gale force at the time and in order that an up-and-down cast be secured the vessel was maneuvered head to the wind and sea with sufficient headway only to prevent her from "falling off." A careful and quick management of the helm under such conditions is necessary, but the maneuver was easily affected and the sounding work carried out with excellent results. When the third station, this same day, however, was to be taken just south of the Grand Banks, it was found that the oceanographic electric winch was burned out. More careful investigation proved the trouble to be so serious that the oceanographic program for the remainder of the cruise would have to be abandoned. Added to this information came the news that

the motor starter of the sonic depth finder had broken. New parts for both these defective ones were the subject of dispatches sent to Washington that night.

An eventful day was March 31 when at 1.55 p. m. we received an S O S flashed from the steamer *Laleham*, without lifeboats and foundering in latitude 39° 06′, longitude 56° 42′. We immediately headed toward the spot and increased speed but other ships (including the *Mauratania*) much nearer responded to the call. At 9 a. m. the steamship *Shirvan* reported having completed the rescue of the crew, so we headed back toward the Tail of the Bank. On account of the S O S call no evening ice broadcast was sent, this being the first time in the history of the ice patrol that such a situation has arisen.

Easter Sunday dawned bright and clear, decidedly the best day experienced so far on the cruise. We started early in the morning searching northward along the eastern side of the Banks, 10 miles seaward of the 100-fathom contour, in a zone which has come to be recognized as the heart of the cold current which bears the freight of ice southward. And so it proved this day, for at 2.45 o'clock in the afternoon the patrol sighted the first ice of the season in the form of broken Arctic fields. The position of this southern tongue was recorded as latitude 43° 59′, longitude 48° 55′. The next morning we ran up to the edge of the ice and from sights found that it had drifted southward during the night at the rate of 1 knot per hour. We steamed about 30 miles northward inshore of the ice skirting its western limits, and returned before nightfall to a position southward of the southern edge. This ice had a very short survival for on the 8th we searched this same area and nothing of it could be seen.

The first and only bergs sighted on the first cruise were raised by the masthead lookout about 2 p. m. on April 9. There were three small bergs in latitude 44° 10′, longitude 47° 51′, which were drifting northeastward at the rate of 0.7 knots per hour. The fact that this ice of small size was floating in water with a temperature of 51° F. (the northern edge of the Gulf Stream), coupled with the report that the *Modoc* was standing eastward to relieve, caused us to head westward this same night and the following day.

The *Tampa* was relieved of the patrol duty the morning of April 11 just to the westward of the Tail. During the cruise we received eight reports of ice from passing vessels; furnished ice information to four ships and received a total of 617 reports of sea-water temperatures.

THE SECOND CRUISE, "MODOC," APRIL 11 TO 25, 1926

After relieving the *Tampa* the *Modoc* was anchored temporarily in on the Grand Bank, but the wind began to freshen on April 12 and before daylight it was found more comfortable to get under way and

head into a moderate westerly gale. The day was spent in this manner with sufficient steerageway only to hold the ship's head up to wind and sea. Due to the fact that we were on the shallowest part of the Bank, the waves were very short and "cobbly," and one sea larger than the others caught our starboard bow just at the right moment, breaking on board and washing a deck box aft beyond the galley. It also bent over and fractured a stanchion which held the forward part of a small canvass awning spread between the cabin and rail. Under such weather conditions as prevailed this day any plans for carrying on a program of ice scouting were forced to be postponed.

April 13 provided better weather and so a start was made to search part of the icy current. At 3 o'clock in the afternoon we reached a position for heading northward along the eastern edge of the Bank, and we paused long enough to hold memorial services for the *Titanic* dead. This ceremony has now become a more or less established custom of the ice patrol vessel each year, and as usual a message was broadcasted to passing ships requesting them to observe a respectful silence from 0700 to 0715 Greenwich civil time, while the actual rites were being paid on the *Modoc*. Early this morning the steamer *Alaunia* informed us that she was stuck fast in an ice field which was located to the south and west of the entrance to the Gulf of St. Lawrence (Cabot Strait). Later this same day this ship discovered a lead and freed herself in open water. Everything was all right with the *Alaunia* when on April 14 she sent the patrol a radio that she had left behind the last of the St. Lawrence fields and was then proceeding eastward past Cape Race.

The *Modoc* made an excursion to the eastward of the Grand Banks on the 14th to the 17th in search of three small bergs reported by a passing vessel. The cruise was a fruitless one as the ice was not located. A great deal of fuel was expended in returning to the westward because of bucking the strong westerly gales and mountainous seas. We finally reached the east edge of the Bank on the 19th instant where the ship remained anchored for the next four days.

The weather made a change for the better on the 22d which was in agreement with the atmospheric pressure distribution as outlined on the meteorological map. This plainly indicated that the pressure gradients were quite small and the progressive movements of the centers of low pressure were relatively slow. All of this pointed toward the advent of summer time conditions and marked a great change from the weather that had prevailed since the inauguration of the patrol. Many reports were received this day from ships on track E bound for St. Lawrence ports. As they crossed from the deep water of the Atlantic on to the continental shelf they sighted

considerable ice, all of which has been listed in detail in "Table of ice and of other obstructions," pages 21 to 30.

The *Modoc* had an opportunity on the 23d instant to search northward along the eastern edge of the Bank for menacing ice. We proceeded northward as far as the forty-fifth parallel but found nothing. We could do nothing more in this line because of foggy conditions, so on April 24 the ship was headed westward in order to meet the relief. The *Tampa* was met about 4 in the afternoon of the 25th. During this cruise the *Modoc* received a total of 53 reports of ice sighted by passing vessels, furnished information to 16 ships, and received a total of 950 reports of sea water temperatures.

THE THIRD CRUISE, "TAMPA," APRIL 25 TO MAY 10, 1926

After effecting the relief and assuming the duties of patrol ship the *Tampa* was kept off on a course for the first one of several oceanographic stations arranged in positions around the Bank in accordance with a previously arranged program. In view of the fact that no ice was south of the forty-fifth parallel and also that there had been considerable postponement in the oceanographic work, the patrol decided the work better be commenced while opportunity existed. Bergs, moreover, were to be expected soon invading the waters around the Tail and it was desirous that the patrol vessel have on board a current map of this critical area.

The next nine days were mostly devoted to collecting data of temperature and salinity from several depths at stations scattered netlike around the Grand Banks. During this period the work was delayed by the presence of a fog and near the latter part of the investigation a strong westerly gale was encountered. While heading the gale on the 2d of May a report was received from the steamship *Rousillon* regarding the position of an iceberg on the east side of the Bank in latitude 44° 10′. This was without doubt one of a group of five bergs that had previously been reported by Cape Race track steamers but it was the southernmost berg so far for 1926 and in that respect was a point of interest for the patrol.

A fog prevented us searching for this berg and so we waited until conditions became clearer. During this period the oceanographer with the data collected calculated the direction and rate of flow of the water in the regions surveyed and a map of the currents was drawn and posted for the information of those in charge of the patrol work. This is the first time in any expedition that the results have been immediately determined on board ship for practical employment.

May 7 the *Tampa* was near the fishing fleet and one vessel was spoken and another was boarded. Sea stores were traded for fresh fish and we anchored for the night in on the Bank. The oceanog-

rapher gave a 15-minute talk this same evening on the history of the ice patrol and general behavior of Arctic ice south of Newfoundland.

Nothing could be done during the day of the 8th on account of fog but the 9th it cleared, the very same day that the patrol ships were meeting on the southwest side of the Bank. Two reports were received from steamers on the east of the slope which had sighted bergs and which plainly indicated that the ice was beginning to drift southward around the Tail. The *Tampa* during the third cruise for the season covered about 1,255 miles, and took 24 oceanographical stations. There were 54 ice reports received and 9 ships were given special ice information. A total of 835 surface temperature reports were contributed by passing vessels. We requested that 22 steamships give receipted acknowledgment for the ice broadcast because their courses were laid near the ice danger zone.

THE FOURTH CRUISE, "MODOC," MAY 10 TO 25, 1926

The *Modoc* met the *Tampa* the morning of May 19, 120 miles west of the Tail, where the oceanographic party was received on board and the relief effected. As soon as the boat was hoisted the *Modoc* was headed eastward with plans to search the region around the Tail the next day. Unfortunately a dense fog shut in before the close of the day which necessarily suspended all searching work. Foggy conditions continued for the next two days but about 5 o'clock the afternoon of the 12th the wind shifted to the westward during a rain squall and the blanket of fog was swept away. We were not slow to take advantage of such ideal conditions and for the next 36 hours conducted a search which led as far north as the 43° 30′ parallel. There were four bergs found in the searched area, the southernmost one on the forty-third parallel in the heart of the Labrador current drifting south-southwest at the rate of 0.8 knots per hour.

The scouting work on the 14th instant revealed more ice than the patrol had found heretofore this year. There were a total of 21 bergs found south of latitude 44° 15′ which was fartherest north for the trip. This ice was strung out along the eastern edge of the Bank and in positions which indicated that the bergs were tending to set on shore and strand. Many of the bergs had growlers near them and it was observed, moreover, that there were no extraordinary large bergs sighted. The rate of drift was estimated at 1.1 knots per hour.

Fog shut in again on the 15th and lasted with occasional brief "light ups" until May 20. During this time the *Modoc* steamed over an area lying off the southwest slope and around the Tail where a total of 12 stations of salinity and temperature were occupied A current map was constructed upon the basis of these data and the

bergs which had been lost in the fog were thought to have drifted either up on the southwest slope of the Bank or to the northeast in the counterset. In any event the current map showed that there was very little likelihood to suppose that the ice had been transported southward in the fog toward the steamship lanes.

Late in the afternoon of the 20th the steamer *Tiger* sighted 20 bergs off the Tail about 30 miles and so during the night we shaped a course so as to be in an advantageous position to commence searching at daylight on the 21st. During the next two or three days the patrol searched this entire area and plotted the positions of a total of 20 bergs and three growlers. As this discussion with sketches is taken up on page 65, it will not be entered upon here. On the 23d it was observed that the bergs farthest offshore to the southeast were slowly being turned in the current and were beginning a counter drift to the northeast. Later in the morning the *Modoc* laid a course to the southward and westward because no chances wished to be taken on bergs drifting unawares in that dangerous direction. While we were steaming in this quarter a fog bank rolled in completely enveloping the ice infested waters.

The approach of the *Tampa* returning for a new tour of duty was announced by radio the night of the 23d and so we headed over to the westward, meeting at a rendezvous about 100 miles west of the Tail. The *Modoc* received 67 reports of ice sighted by passing vessels, furnished ice information to 10 ships, requested acknowledgment from 22 vessels for the regular ice broadcast, and received 775 surface temperature reports during the cruise thus terminated.

THE FIFTH CRUISE, "TAMPA," MAY 25 TO JUNE 10, 1926

After relieving the *Modoc* the *Tampa* stood eastward toward the group of bergs last seen by the *Modoc* on the 23d instant but fog shut in the morning of the 26th causing us to drift until the arrival of clear weather again. Sometime during the morning we received a radio from the steamer *Clearpool* reporting a berg and growler in latitude 41° 49′, longitude 50° 12′. We immediately requested the master of the *Clearpool* to verify his position and indicate how recently he had obtained astronomical sights, because this position was considered surprisingly far south for any berg to drift so quickly. The reply stated that the previous position was in error and gave the latitude as 42° 24′. The *Tampa* got under way and had not proceeded very far when a growler was sighted close aboard in the fog. This we thought might be the same growler that the *Clearpool* had seen earlier in the day, so taking it as a point of departure we headed eastward about 10 miles where a berg was found. When the fog cleared later on we beheld five bergs in sight to the eastward, and so we steamed over to the largest one. This group of bergs was

undoubtedly part of the same ice which the *Modoc* located to the northeastward on the last cruise.

The fog cleared up for good on the morning of the 27th and gave us an opportunity not only to locate all the bergs in this region south of the Tail but also permitted of securing accurate sights. We had been without a definite fix of the ship's position for nearly four days. Ten bergs were sighted during the day, five in the dead water directly south of the Tail, latitude 42° 27′; two lay to the westward on about the same parallel but in longitude 51°; and three more bergs were observed grouped together at the farthest point south for the year, viz, latitude 42° 13′ longitude 50° 29′. The distribution of this last lot was in agreement with the oceanic circulation as determined May 18–20 by the *Modoc*. The bergs in longitude 51° 00′ had drifted as far west as was possible on account of the counterset in that region, while the three southern ones had become caught in the inshore edge of the easterly flowing water and they were drifting east-southeastward at the rate of 0.5 of a knot per hour.

On May 28 a message was received from the steamship *Chicago* reporting a berg in latitude 41° 51′, longitude 48° 33′; this being the southernmost ice and only about 20 miles north of the westbound steamer track, the *Tampa* was headed on an easterly course in order to get in touch with this ice as soon as possible. At daylight on the 29th we sighted the berg for which we were in search. It was not a very large berg, in fact it was medium to small and it showed signs of rapid disintegration. During the morning and afternoon demolition operations were carried on, making use of 6-pounder gun and 238-pound TNT mines. Considerable ice was shaken down but it is questionable whether the expenditure would be justifiable in continuing such a practice on a greater scale. That evening we spent close to the ice warning all approaching ships of its location.

The next day our berg was only about half of its former size. The rapid disintegration was due without doubt to a heavy swell which continually washed the ice and broke off growlers one after another. The temperature of the water, 56°, of course also materially assisted to speed up the melting processes, and so May 31 witnessed the entire removal of this menace to navigation. This was the most rapid disintegration of which the patrol has record, to the best of our knowledge, and it is of interest because it was due in a great measure to the swell and sea which continually lashed and strained the berg. At 12.30 p. m. there was no longer any reason for remaining in the locality—latitude 40° 45′, longitude 47° 38′—so we steamed ahead on course 310° toward the group of five bergs which we had left on the 28th instant.

About 7 o'clock the morning of June 1 the steamer *Stadsdijk* reported seeing two bergs about 30 miles to the westward of where we were searching and this ice was believed to be the same that we

wished to sight. The course was accordingly changed for this new position and at the same time radiocompass bearings were taken of the *Stadsdijk*. While we were maneuvering to get in touch with this ice a message was received from the steamship *George Washington* that she had just passed a small berg about 35 miles to the eastward of where we were then and on the westbound steamer track. We immediately headed that way, made contact with the *Washington* at 11 o'clock, and picked up the berg just before sunset.

The *Tampa* remained close to this berg during the next four days, as long as it continued to be a menace to navigation. During the nighttime it was our practice upon the approach of steamers to throw the searchlight beam on the ice clearly marking its position. That this was appreciated is shown by the following message from the steamship *Mauretania*, which passed close to the *Tampa* one night. "We are passing south of you; can see berg in your searchlight beam. Thank you. Rostron."

A dispatch on June 2 broadcasted from Arlington radio station stated that the trans-Atlantic track conference had decided to change from tracks B to tracks A immediately, the eastbound track being moved June 2 to 39° 30′ latitude, and the westbound track being moved simultaneously to latitude 41°, with the complete shift of the westbound to latitude 40° 30′ on the 9th instant.

On June 4, with the melting of the aforementioned berg, the patrol vessel shifted its position 4 miles to the northward near a large berg which had been sighted the previous day. A survey was made of the exposed surface above water; a tower, the highest point on one end, measured 55 feet; the opposite end, 35 feet; and the length was 382 feet. It is worth mentioning here that the heights of bergs can be measured quite accurately by climbing the mast to a point where the line of sight of the observer passes tangent to the summit of the ice and through the horizon. A correction of 4 feet should be added to this as the correction for the dip of the horizon. Measured heights from the water line can be easily marked upon the mast in units of 5 feet, and it will seldom be found that heights of bergs will exceed the height of the crow's nest.

While the *Tampa* was lying alongside of this ice on June 5 the steamer *Leviathan* passed close aboard about 9 o'clock in the morning. She thanked the patrol for its services and very complimentary added, "Your vigilance was an inspiring sight to everybody on board. Hartley." Captain Fisher replied, "Glad to be of service to the queen of the American merchant marine. Your passing ship was an inspiring and beautiful sight." The early morning hours of June 6 witnessed the complete melting of this ice.

The last few days of the *Tampa's* cruise were spent patrolling along the southern boundary of the fog wall as it was impossible to carry on any ice scouting in the cold waters to the northward. The

Tampa received a total of 970 sea water temperatures from passing vessels; gave special ice information to 10 ships; and received a total of 159 reports of ice. There were 71 ships during the cruise from which we requested acknowledgment of receipt of the ice broadcast.

THE SIXTH CRUISE, "MODOC," JUNE 10 TO 25, 1926

The 11th and 12th were foggy days but June 13 it cleared and the *Modoc* was headed westward in order to get into an advantageous position for searching for any ice south of the Tail of the Bank. Excellent visibility prevailed on the 14th and the *Modoc* for the second day of clear weather was cruised at forced draft over a large area where bergs were suspected. No ice was found, however, and this fact was interpreted as indicating a great dwindling in the number of bergs from the high point earlier in the month. Not over three weeks previously in this same locality there were drifting more than 20 icebergs. A few reports continued to be received from steamers on the Cape Race tracks to the northward.

The 15th of June the *Modoc* spent searching from a point 70 miles west of the Tail along the forty-third parallel to the eastward about 90 miles. No ice was sighted and excellent visibility prevailed the entire day except for a short time in the afternoon. When we attempted to search northward, however, along the eastern slope of the Bank a wall of fog was met. The water along the slope, with a temperature of 46°, was 4° or 5° cooler than any other part of the surrounding surface water.

During the morning of the 16th we made another attempt to search northward along the east edge of the Bank but a heavy fog wall was soon entered which of course precluded all hopes of further ice search. The afternoon and evening were spent occupying a line of oceanographic stations extending south of the Tail, but this work had to be abandoned late at night due to a severe southerly storm and sea.

The storm ended on the 17th as suddenly as it had begun so we were quick to take advantage of the clear visibility searching northward as far as latitude 44° 30′ in the icy current. No ice was found in the current and this was taken as a very hopeful sign that there would be very few bergs able to drift as far as the Tail during the rest of 1926. A small berg was reported well to the northwestward on the southwest part of Bank, however, but its position was not dangerous, and it was believed this ice was the same as that reported on the 13th instant to the patrol, then grounded on the Tail.

We were able to continue the patrol's search on the 18th still farther to the northward, no bergs being found south of parallel 44° 45′. We anchored on the eastern side of the Bank on the 19th and 20th. The steamer *United States* sighted a small berg southeast of the Tail about 20 miles on the 19th but inasmuch as it was not

much larger than a growler in size and that it was floating in warm water, temperature 55°, it was not regarded as a potential menace. We searched this vicinity on the 22d, however, the first opportunity of clear weather but nothing was found so the *Modoc* was headed westward for a rendezvous with the relief ship.

There were 144 reports of ice received from passing vessels; 3 steamers were furnished special ice information upon request; and a total of 1,002 reports of surface water temperatures were received.

THE SEVENTH CRUISE, "TAMPA," JUNE 25 TO 30, 1926

After taking over the patrol work from the *Modoc* it was decided best to utilize the time compiling an ocean current map of the region around the Tail of the Bank, in order that a record might be made of the current conditions just before the patrol was discontinued. Stations were occupied along lines normal to the trend of the slope and spaced at intervals of 50 to 75 miles.

This work continued and the 26th found the *Tampa* running northward on a line just south of the Tail. The water temperature wall was found to lie in latitude 41° 55′, longitude 50° 15′, the thermometer dropping from 61° to 57° quite abruptly. The position of the temperature wall at this place refutes the belief that the position of the Atlantic water had been changed much from that found earlier in the season. Such an error of judgment is easily made because of the relatively high temperature of the surface water which is attained solely as an effect of the sun's heat with the approach of summer.

The 27th, 28th, and 29th were spent on oceanographic survey and when the weather was clear advantage was taken to include a search for ice. Not a sign of bergs was found and so a recommendation was forwarded to headquarters that the patrol be discontinued at midnight on June 30. A reply the next day directed the patrol to discontinue its activities at midnight June 30 and return to the United States.

We headed westward on the last day of the month preparatory to returning to Boston. No ice had been reported or sighted by the patrol vessel south of the forty-fourth parallel since June 17 and this area had been repeatedly searched since that date. We were quite confident that no ice could possibly be in these waters. Bergs continued to be reported on the northern part of the Bank and near Cape Race as is usually the case at this time of the year. Messages were dispatched to the wireless officer, Halifax; the officer in charge radiocompass station, Cape Race; and the commercial wireless station, Cape Race, notifying them all of the discontinuation of the ice patrol and thanking them for cooperation during the 1926 season.

During the cruise thus terminated the *Tampa* received 36 reports of ice, furnished special ice information upon request to 1 steamship, and received a total of 186 sea-water temperature reports.

RADIO COMMUNICATIONS

The vital importance of the radio to the plan of an ice patrol warning approaching ships of the dangers in their paths is quite obvious. It would be literally impossible to perform this humanitarian service if it were not for Marconi's pioneer invention. Naturally the efficiency and value of the patrol, as it proportionately assists to increase the safety of life on the North Atlantic, is closely wrapped up in the entire subject of radio. Not only is it the ice which is actually found by the patrol that is reported to shipping, but also is included the ice from a much larger area than that which the patrol could possibly hope to cover. Such accomplishments can only be realized with the cooperative assistance received from passing ships which report to the patrol from positions scattered over the entire danger region. It can be seen that under such circumstances the patrol vessel assumes the rôle of a radio clearing house and thus becomes the disseminator of a digested report for the whole region. The story of the past season's work, as in former years, has been one of willing and efficient service on the part of the merchant vessels. We also want to add that the Canadian direction-finding stations and the Cape Race Commercial Radio Station have done everything possible to make the radio operations run smoothly and successfully. The summary of the work performed during the 1926 season will be found in the report of the ice patrol commander, page 17.

A survey of the radio communications during 1926 particularly impresses us with a feature which excels previous years; and the part we have in mind refers to the great improvement regarding the ship to shore communication. The patrol, in its early years, depended upon forwarding its traffic to Washington via the nearest coastal station, Cape Race, Newfoundland, by means of an ordinary 2-kilowatt spark transmitter. There were, however, times during the first few weeks of the ice season, say until April 1, when direct communication was possible by this means, but for the major part of the season, it was necessary to transmit messages via Cape Race.

Because of the expensive tariffs by this route it has long been the desire to establish official communication between the patrol and naval radio stations situated in the United States. When the then new ships *Tampa* and *Modoc*, in 1922, were assigned to patrol duty, more frequent communication with United States coastal stations was effected by means of arc sets with which these vessels were

equipped. This service failed quite often, however, due to summer time static conditions and poor functioning of the sets. Such unsatisfactory conditions caused the officials in charge of the patrol work in 1925 to equip the ships with 2-kilowatt vacuum tube transmitters, especially designed and manufactured by the General Electric Co. (See Ice Patrol Bull. No. 13, p. 51.) Communication by means of these sets with the naval coastal station at Bar Harbor, Me., was more reliable and satisfactory than at any time during patrol history. Summer time static conditions even then, quite frequently in June, necessitated an auxiliary service, communication being effected via the patrol ship off duty in Halifax. Realizing the natural difficulties which the patrol had met for several years with ship-to-shore traffic, a new type of set was installed just before the ships sailed in 1926. This set employs a short-wave, high-frequency transmitter, 35 or 70 meters, and it represents a new design which the United States Navy is manufacturing. In fact the work was rushed in order that the patrol might be equipped for 1926. During the first half of the season minor alterations were found necessary before the best performance was attained, but by the latter part of the patrol the sets were operating satisfactory. Direct communication with the high-frequency sets was maintained with few exceptions the entire patrol of 1926 with the Navy Experimental Laboratory, Bellevue, Md. The set is described as a Navy model "XA," 500-watt crystal control, with a frequency of 4,205 and 8,410 kilocycles, and was manufactured at the laboratory, Bellevue.

The other radio equipment carried on board the ice patrol vessels was the same as that in use during the 1925 patrol. (See Ice Patrol Bull. No. 13, pp. 51–52.) Information regarding the weather was broadcasted every night and morning by means of the 2-kilowatt tube transmitter (C. G. model T–2). Also information of a general character as to the behavior and distribution of ice and currents were "talked" quite informally this past year as the steamers approached the ice regions. The officers of these vessels were especially invited to come to the radio room and listen in and it was apparent that these phone talks were of considerable value. It is human to forget with the passage of time even the lessons learned through great tragedies, and the mariner is no exception to this rule. It is, we believe, part of the spirit of ice patrol, to educate by talks on the entire subject of this danger every spring. The patrol has trained experts and it is certain that their knowledge will be of interest and stimulate educational thought along similar lines with the navigator.

The amount of ice patrol traffic handled by radio is always interesting and indicative of the amount of work performed by that means. There were approximately 5,488 reports received from pass-

ing steamers concerning their position, course, speed, and sea water temperature. A total of 470 official messages were transmitted to Washington, and 236 were received. It is estimated that a total of 252,299 words were handled during the season of 1926. (See p. 20.)

There is appended herewith a schedule giving the times at which messages were sent and received by the patrol vessel. The schedule was not adopted until after several preliminary experiments and trials, so that the final draft as outlined here ought to furnish a very good schedule upon which to base radio operations for next year.

(All times seventy-fifth meridian)

0600. Ice broadcast (spark); call on 600 meters then send on 706 meters twice with a two-minute interval.

0700. Ice broadcast (continuous wave); call on 600 meters then send twice on 1,713 meters with two-minute interval.

0800. Send weather report to Bar Harbor, Me., on 1,713 meters, using "no answer" method.

0915. Copy Cape Race weather broadcast.

1030. Copy Arlington weather broadcast.

1200. Copy time signals and ice patrol traffic from Arlington.

1415. Copy weather broadcast from Cape Race.

1800. Ice broadcast (spark); call on 600 meters then send on 706 meters twice with two-minute interval.

1900. Ice broadcast (continuous wave); call on 600 meters then send on 1,713 meters with a two-minute interval.

1930. Clear all ship to shore traffic with Navy Experimental Laboratory, Bellevue, Md., on 35 meters.

2000. Stand-by schedule with Bar Harbor, Me., on 1,713 meters only in case the 1,930 schedule fails.

2115. Copy Cape Race weather broadcast.

2200. Copy time signals and any ice patrol traffic from Arlington.

2230. Copy weather broadcast from Arlington.

SUMMARY REPORT OF ICE PATROL COMMANDER

Commander H. G. Fisher, Commander International Ice Patrol

Ice patrol was inaugurated March 25, when the *Tampa* sailed from Boston for the Grand Banks. The *Modoc* departed from New York in sufficient time to relieve the *Tampa* on April 11, and thereafter these two ships took alternate 15-day tours of duty throughout the ice season. The patrol was discontinued at midnight June 30, having been on guard a total of 97 days.

The ice patrol which is now 13 years of age, has during this period had opportunity to study its problems, and plan its general administration so that now many of the features of the work have become systematized, especially those events which have gradually grown to assume a more or less routine character. The work, as has often been remarked, possesses two main aspects—(*a*) the practical and (*b*) the theoretical. The first (*a*) embraces the primary function of locating by actual scouting and radio communication, the icebergs and field ice nearest to and menacing the North Atlantic lane routes, and the duty of placing that information at the disposal of all approaching trans-Atlantic ships. The second (*b*) centers on carrying out an intelligent scientific program the results of which throw light of practical importance on the economic humanitarian service which the patrol endeavors to render to shipping.

In speaking of the practical work it is customary to include in the summary report of each year a brief review of the distribution of ice in time and place, its drift, numbers of bergs, and a survey of the weather which has been experienced during the season. It may be quite confidently stated that less field ice drifted south of Newfoundland in 1926 than usual. In fact there were very few reports of field ice before the month of March with the flat ice attaining a maximum early in April, and with the last report dated May 11. Even at the date of its most southern extension, April 4 and 5, it did not reach as far as the Tail of the Bank, nor did it spread to any great extent over the Grand Banks south of Newfoundland as it often does. It held, however, more or less closely to the eastern and northern portions of the Grand Bank as usual.

Ice conditions in the Gulf of St. Lawrence this year were very open, the patrol receiving a message from the Canadian ice patrol ship *Mikula* that the gulf and river were navigable to Quebec on April 18, or about one month earlier than usual.

The first icebergs were reported south of Newfoundland in February; the number increased in March. No bergs drifted south of the Tail during April; few during the first half of May; but the latter half of that month saw the greatest number of bergs for the season. After June 6 no bergs of any size drifted south of the Bank. The total number of bergs drifting south of Newfoundland during 1926 was nearly normal but the seasonal distribution was not. (See p. 72.) Three bergs drifted much farther south than the others, crossing the westbound steamship lane route, known as track B. Due to the presence of this ice in such menacing positions the tracks were shifted to A, 60 miles farther south from June 5 to 30. As previously stated there were reports of only two bergs of any consequence in June around the Tail of the Bank, one on the 12th and the other on the 17th. The last two weeks of that month these waters were free of ice and under such conditions consequently it was considered safe to discontinue the patrol on June 30.

A considerable number of bergs, it should be added, were reported on the northern part of the Bank, from May on throughout the ice season.

The patrol was treated to an unusually long rough spell of weather persisting to the latter part of April before the backbone of winter was finally broken. This agrees quite closely with the seasonal change to the westward over the United States when winter conditions prevailed unusually late into the spring of 1926. Winter atmospheric circulation of the ice regions differs quite markedly from summer time conditions. The Grand Banks south of Newfoundland are located on the southern side of a cyclonic wind system caused by the normal winter distribution of atmospheric pressures. The barometric gradients are exceedingly steep, causing westerly gales to blow with great and constant intensity for several days at a time, though they are often interrupted by low centers of marked disturbance, moving along a northeasterly track to die offshore in the Atlantic. It can be imagined that under such severe handicaps as prevailed this year, March 25 to April 22, little work of any value could be carried on. By the same token it is considered unwise in any year to inaugurate the patrol work so long as winter conditions persist.

The scientific work carried on this season was under the supervision of Lieutenant Commander Smith, who returned to the patrol after spending a year abroad on two of the most important natural problems which have for some time confronted us, viz (*a*) information regarding the probable drift of ice after arriving at the Tail of the Grand Banks, and (*b*) advance information about the annual amount of ice to be expected south of Newfoundland. The former subject is discussed under the section devoted to oceanography; the latter is taken up under the heading "Weather."

A notable advance in this year's work was the employment of dynamic methods to determine and map the currents around the Grand Banks. A special bulletin, No. 14, describing the work for use on ice patrol, has recently been published by the Coast Guard. The final answer as to the degree of success attending it depends on its practical employment on future ice patrols. It would be very wise and advisable if officers of the Coast Guard detailed to patrol duty were required to acquaint themselves with these methods in order that several may possess this knowledge instead of only one officer, as is now the case. The international ice patrol will give its most efficient and economic service to shipping only when useful scientific methods are employed to support the practical work.

The patrol ships were equipped this year with practically the same outfits as they had on board in 1925, with the exception of new high-frequency radio sets, especially intended for use in communication with shore, and a second electric salinity set so that determinations might be made on board both ships instead of on one alone, as in previous seasons. The performance of the new radio sets for ship-to-shore communication, as stated in more detail under the section devoted to communications, page 14, well repaid the expense and effort expended in placing the apparatus on board.

About 465 hydrographical soundings by means of the sonic apparatus were made during the season at various positions both in the shallow waters over the Grand Bank and offshore, particularly to the southward of the Bank in the deeper portions of the Atlantic Basin. These are described under the section devoted to sonic sounding, page 49. The value of carrying on this work on future patrols is emphasized, and in this connection it is believed that both ice patrol vessels ought to be equipped with sonic depth apparatus instead of one, as is now the case; steps also ought to be taken to have at all times at least one trained operator on board.

About 450 steamships are known to have taken advantage of the services offered by the ice patrol in 1926. No doubt several other ships of which there is no mention also listened-in for the daily broadcasts. The following list is submitted in order that the reader may gain an idea of the service which is being given the ships of many nationalities. The masters of these vessels have been individually thanked, by letter, by the chairman of the interdepartmental board in charge of ice patrol.

Belgian	8	Danish	8	Greek	1	Argentian	1
British	171	Dutch	25	Italian	9	Spanish	5
Canadian	27	French	13	Japanese	1	Swedish	11
Chilean	1	German	14	Norwegian	20	United States	114

A summary of work performed, the dissemination of information, and other miscellaneous business handled by the Patrol for 1926 follows:

Washington official messages	470
Daily routine broadcasts	372
Special broadcasts (during fog)	42
Ice information to certain vessels, special	165
Special ice information requested	48
Position reports requested	1
Track information requested	4
Chronometer comparisons	1
Weather reports	102
Water temperature reports received	5,488
Ice reports received from:	
Steamships	414
Cape Race	172
Words handled by radio	252,299
Violation of steamship tracks reported	1
S O S not in jurisdiction of Patrol vessels	4

As in previous years, the cooperation received from passing ships was generous and indicative of a sincere appreciation of this service, which is being financially supported by international contribution. The commander of the ice patrol takes this opportunity to thank all those who assisted to make the past season's work successful.

TABLE OF ICE AND OF OTHER OBSTRUCTIONS, 1926

Date	No.	Vessel reporting	Position		Nature of ice or obstruction
			Latitude, north	Longitude, west	
			° ′	° ′	
Feb. 8	1	Cape Race (station)	48 11	49 13	Slush ice.
10	2	do	48 15	49 40	Field ice east of St. Johns.
10	3	do	47 25 to 47 08	49 50 to 51 05	Occasional patches field ice.
10	4	do	44 53	59 52	Field ice.
15	5	do	Bull Head to Canso.		Do.
16	6	do	100 miles NE. Cape Race.		Do.
17	7	do	Along the coast		Heavy ice field.
19	8	do	44 46 to 44 40	58 57 to 60 28	Do.
20	9	do	48 09 to 48 06	48 07 to 49 20	Do.
20	10	do	47 50	50 04	Slab ice and small bergs.
21	11	do	45 15	59 44	Field ice.
21	12	do	47 17	47 03	Several small bergs.
22	13	do	41 04	37 40	Derelict schooner Cecil jr.
Mar. 2	14	do	48 16 to 47 40	46 50 to 47 50	Small bergs and growlers.
2	15	do	45 07 to 45 05	57 13 to 57 42	Field ice.
6	16	do	48 24	46 22	Do.
15	17	do	47 50	49 38	Field ice and occasional bergs.
16	18	do	47 24	50 57	Field ice.
18	19	do	47 54 to 46 57	47 58 to 48 45	Heavy field ice and small bergs.
19	20	do	46 56	47 49	Field ice and growlers.
19	21	do	45 00 to 45 30	58 20 to 57 40	Field ice.
19	22	do	45 40 to 46 05	47 00 to 46 25	Field ice and large growlers.
20	23	do	46 20 to 45 40	46 40 to 48 30	Do.
20	24	do	45 38	46 23	Small bergs.
20	25	do	45 41	46 03	1 berg.
20	26	do	46 20 to 45 40	46 40 to 48 30	Field ice and growlers.
20	27	do	45 10	46 30	Large bergs.
20	28	do	45 15	46 45	Small berg.
20	29	do	45 16	47 29	Large berg.
20	30	do	45 17	47 46	Do.
20	31	do	45 09	48 35	Do.
21	32	do	44 55	46 23	Growlers.
21	33	do	44 50	48 30	Numerous growlers; field ice.
22	34	do	44 35	57 20	Field ice.
22	35	do	44 22	48 36	Field ice and growlers.
22	36	do	44 18	48 36	Small berg.
20	37	Hydrographic Office	45 17	46 30	4 large bergs.
20	38	do	45 30	48 10	3 bergs.
21	39	do	45 15	48 10	Large ice field.
23	40	Naturia	48 10	48 00	Large ice field; growlers.
23	41	Cape Race (station)	48 20	49 15	Field ice.
23	42	do	43 47 to 43 43	48 28 to 48 41	Field ice and growlers.
25	43	do	43 45	48 07	Do.
25	44	do	48 45 to 48 00	49 20 to 48 00	Field ice.
25	45	do	45 50	47 20	Do.

Table of ice and of other obstructions, 1926—Continued

Date	No.	Vessel reporting	Position: Latitude, north	Position: Longitude, west	Nature of ice or obstruction
			° ′	° ′	
Mar. 26	46	Cape Race (station)	42 51	58 04	Spar attached to wreckage.
27	47	do	47 00	48 00	Large bergs.

WEATHER—A BRIEF REVIEW OF THE 1926 ICE SEASON

Edward H. Smith

As we sit down to write a worth-while, instructive report on the subject of weather, as it concerned the ice patrol of 1926, and in a sense as it probably concerns future patrols, we believe it most important to survey first only the principal features which were responsible in characterizing the 1926 season as a whole. Under this category comes foremost the steepness of the barometric gradients and the consequent great intensity of the winds that blew so constantly from the day we left Boston, March 25, until well along in April. It is impossible, of course, to place one's finger upon any definite date when a meteorological phenomenon such as we call "wintertime" conditions change to "summertime" conditions. This spring on the Grand Banks, however, we are convinced, that wintertime conditions prevailed longer than usual, and it was not until the latter part of April that we began to notice a slackening in the wind force, a dropping off in the frequency of storms, and a lessening in the tendency of great anticyclones to build up and spread eastward from the North American Continent. It also can be stated with considerable assurance that the atmospheric envelope was in a violent state of agitation from March 29 to April 20. During this period of 22 days the wind blew with gale force on 12 days, and there were only 2 days on which it did not attain a fresh to a strong breeze on the Beaufort scale. Before passing on from the remarks on wintertime meteorological conditions we should like to familiarize everyone with the general scheme of the air streams under which the ice regions come.

THE TWO MAJOR WEATHER TYPES WHICH PREVAIL IN THE ICE REGIONS

The ice season extending as it does from March to July bridges two main types of weather which standing at either end of the gamut we have termed wintertime and summertime conditions. This all important seasonal effect is of course superimposed upon the fundamental planetary system of circulation and is directly due to the thermal seesaw which is continually in process between land and water masses. In the North Atlantic (and controlling the weather of the ice regions), we have three great centers of action, triangularly located and with the relative condition of each determining the consequent behavior of the air: (*a*) the Icelandic minimum; (*b*) the

Azorean high; and (c) the continental effect of bordering land areas. Glancing at the normal isobaric map of the North Atlantic for the colder months of the year, the station normals of which are based upon average barometric records compiled over a long series of years, our eye is immediately caught by a huge elliptical-shaped depression near Iceland. And then we notice that in effect this depression is emphasized by the opposing anticyclonic conditions which prevail over the bordering land masses of the Atlantic basin. The geographical position of the Grand Banks in the western North Atlantic on the southwestern side of this mammoth cyclonic wind system, it is plain to see, subjects the iceberg regions south of Newfoundland to an air stream flowing from west to east, the swiftness of which is gale force the major part of the early season. Such prevailing circulation is, however, often subjected to short interruptions when cyclonic storm centers usually of marked intensity come from the United States and cross the ice regions. Now, during the latter half of the ice season the unequal rate of solar warming between land and water causes the wintertime high pressure to transfer from the land and increase over the ocean, thereby placing the Grand Banks region on the northwest side of a huge clockwise wind system. Gradients also become much reduced in steepness from what are found in winter season, and the warm southerly winds blowing over the icy waters around the Grand Banks bring a fog sheet which often does not lift for weeks at a time. This comprises a general survey of the two main types of weather and incidently it emphasizes two of the greatest handicaps the patrol is forced to encounter, namely early season gales and later season fogs.

If we return to a survey of the 1926 ice season we find no features of especial significance beyond the continuance of cyclone and anticyclone in alternate sequence following each other across the meteorological map from west to east, and in general with the progress of the season, gradients becoming gentler, winds weaker, and vortices traveling slower.

An interruption in the regularity of undulations to which the troposphere was subjected by alternate "highs" and "lows," occurred May 27 to June 2, when a great anticyclone built up and spread over the entire Atlantic seaboard from Florida to Newfoundland. It is rare to have such an atmospheric distribution but it means clear visibility and northerly winds for the ice regions; really the best weather we get on patrol.

DEVELOPMENT OF SUMMER TIME CONDITIONS

Going into June we began to notice the gradual development of the summer time Azorean high pressure as the thermal seesaw swung the opposite way from that observed at the beginning of the ice season.

At this time southwesterly winds began to blow with greater frequency and longer duration along the Atlantic seaboard of North America, and the ice regions being in the periphery of this system came under the effects of the southwest air stream more and more. The first real evidences of a hot wave over the United States was perceived the latter part of June.

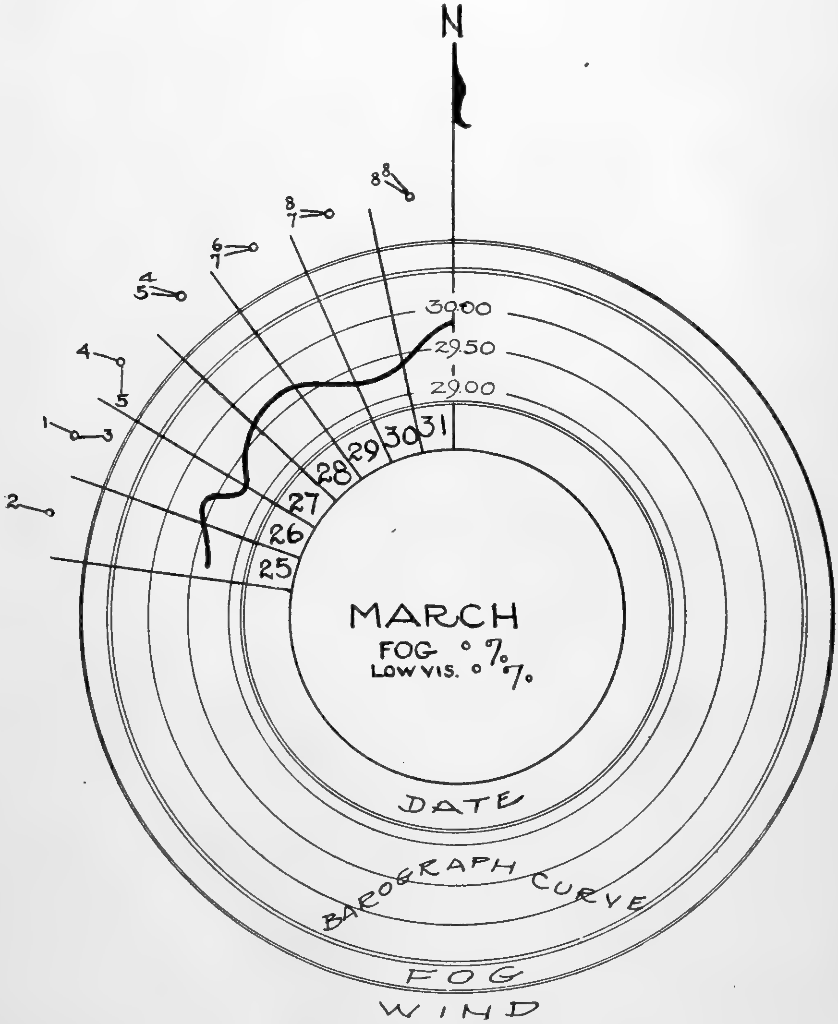

FIG. 1.—March weather diagram

WEATHER DIAGRAMS

In order to secure an intelligent impression of the general weather conditions which prevailed in the ice regions during 1926 we have constructed circular diagrams which include by months the following

information: Each diagram represents a month's time and is divided into 30 or 31 equal sectors in accordance with the number of days. The outer margin gives the wind direction averaged for each 12-hour period and also the force in terms of Beaufort scale. The next adjacent ring contains information on the amount of fog and

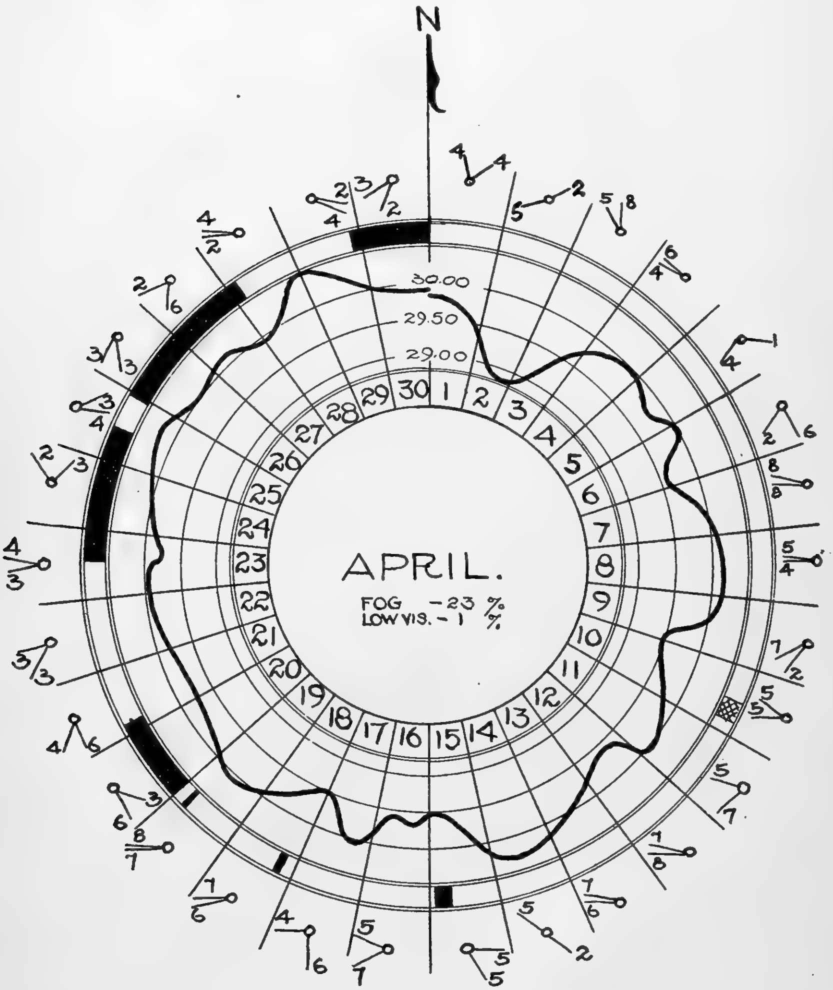

FIG. 2.—April weather diagram

low visibility experienced during the month; the fog is filled in full black and the low visibility in crosshatched shading. The third band in contains a continuous barograph record for the entire month and is drawn to scale. The numerals on the innermost ring signify the days of the month.

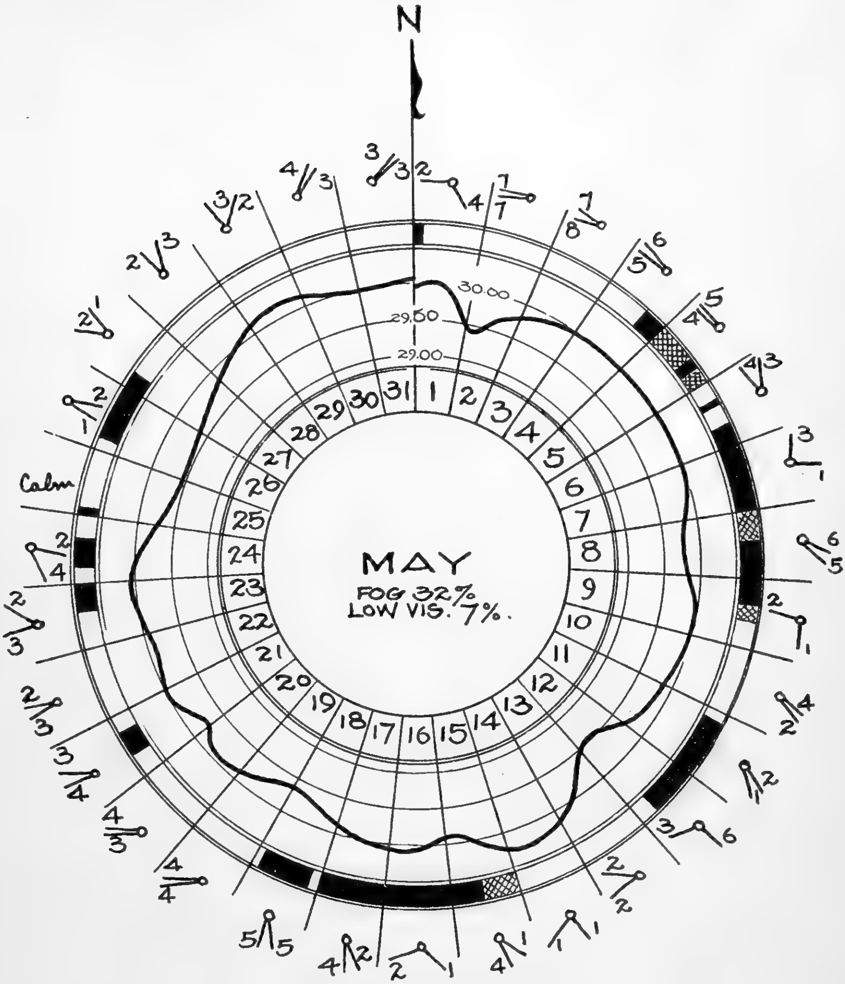

FIG. 3.—May weather diagram

Month	Percentage (hours)		Gales (number of days)[1]	Winds (average force)	Calms (number)[2]
	Fog	Low visibility			
March:					
Actual	0	0	3	5.0	0
Pilot chart	31				
April:					
Actual	23	1	9	3.8	0
Pilot chart	42				
May:					
Actual	32	7	2	3.1	1
Pilot chart	33				
June:					
Actual	12	[illegible]	0	2.8	2
Pilot chart	55				

[1] Based on 6 days in March. Gales per 12-hour periods.

[2] Based on 12-hour periods.

Fog was noticeably less than normal during April, normal during May, and very deficient in June. The absence of fog in this latter month is partly attributed to the fact that the position of the patrol vessel was unusually far south in the Gulf Stream during the first

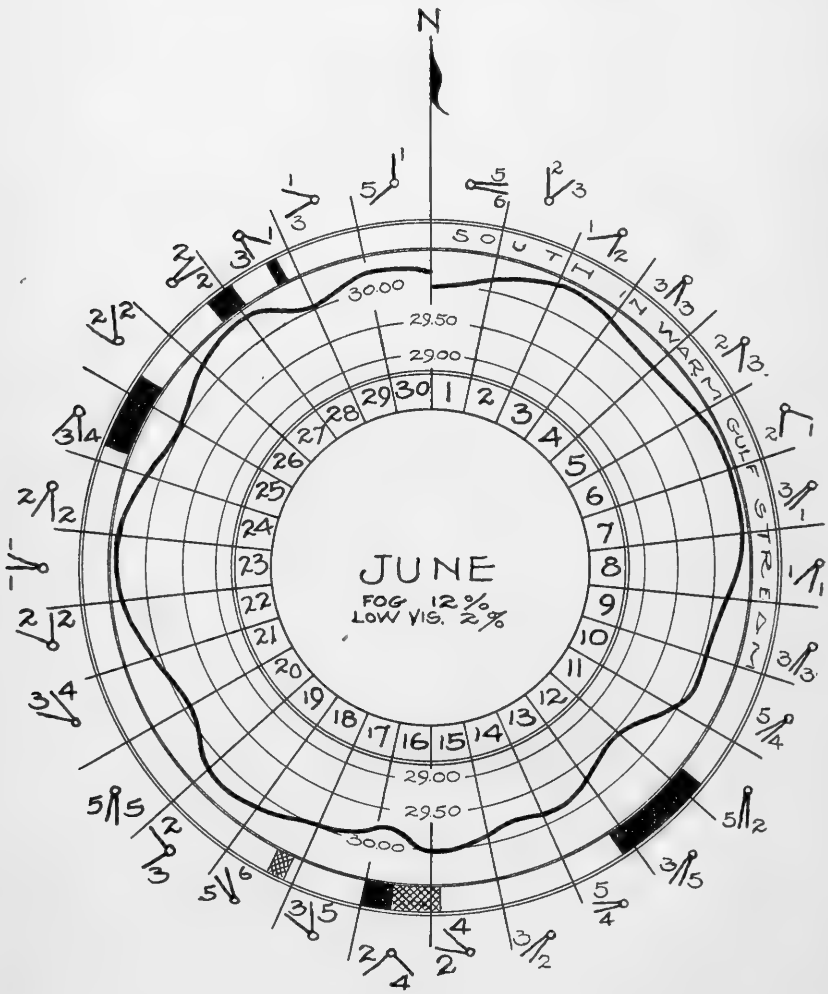

FIG. 4.—June weather diagram

half of the month and thus experienced clear weather. If she had been in the cold waters around the Tail of the Bank it is believed that almost constant fog would have been the order of the days.

CYCLONE TRACKS

Since the development and the passage of cyclones from the interior of the United States out across the ice regions is one of the most absorbing meteorological events with which we deal on patrol, per-

haps it will be of interest and instruction to describe the paths of some of the cyclones, rate of motion, and sequence in the procession which was observed.

MARCH

The weather conditions on March 25, our sailing day from Boston, consisted of a trough of low pressure stretched along the Ohio and St. Lawrence River Valleys and embracing a well marked center which was progressing northeastward. It was rather interesting to watch the path of this disturbance which has been plotted on Figure 5, page 38, as track A. The center, during the night of March 26, curved to the right and followed a southeasterly path to the vicinity of Sable Island. At 8 a. m. on the 27th it was located again on the weather map off Sydney, Cape Breton, and thence it moved in the more frequently traveled route toward the northeast. The excursion to the southward of the usual cyclone path was attributed in this case to the presence of a deficiency of pressure over the Carolinas combined with the blocking influence of a high pressure area to the northward. The subsequent behavior of this disturbance is worth a word or two. It can be seen by Figure 5, page 38, that the center moved northeastward for two days when somewhere east of Newfoundland it deepened and thus intensifying the gradient gave to the Grand Banks region strong westerly winds for several days. On March 31 an excess of air accumulated to the westward over the United States in sufficient proportions finally to remove all effects of our storm offshore into the ocean. (For a daily record of winds, pressures, and fog, reference may be made to the weather diagram, fig. 1, p. 33.)

APRIL

During the early part of the ice season the atmospheric envelope we repeat for emphasis, is usually in violent agitation; rocked intermittently, so to speak, as successive cyclonic vortices disturb the prevailing atmospheric pressure distribution. The normal pressure character for this time of year is one to which we have previously referred as wintertime, and is clearly identified by a dominating excess of pressure lying over the cold continental area as compared with the air mass over the warmer ocean. No sooner had March 31 marked the disappearance to the eastward of the storm center described above than it also ushered in a similar vortex in the troposphere, first noticed on our map for the eastern United States just south of Chicago, Ill. The career of this cyclone across the country and out to sea, March 31 to April 3, has been traced as track B, Figure 5, page 38. The effect of its approach was first detected when at a distance of 500 miles from the ice patrol ship, the barometric pressure began to fall the afternoon of April 1. The northwesterly winds which had been blowing with great intensity and duration ceased about this

time and a breeze sprang up from the northeast. The barometer continued to fall until noon the 2d, when it recorded what proved to be the minimum for the entire patrol (28.90; see weather diagram for April), and the depression must have passed about over our position south of Newfoundland. The winds with the passing of the center almost immediately shifted to northwest and increased that night to gale force. While we were still within the effects of the storm described above, a region of new depression was observed over the lower Mississippi River Valley. The path followed by this disturbance from April 2 to 7 is shown as track D, Figure 5. This center traveled along a path located a little farther to the northward than that of its predecessor. It followed a straight line more or less

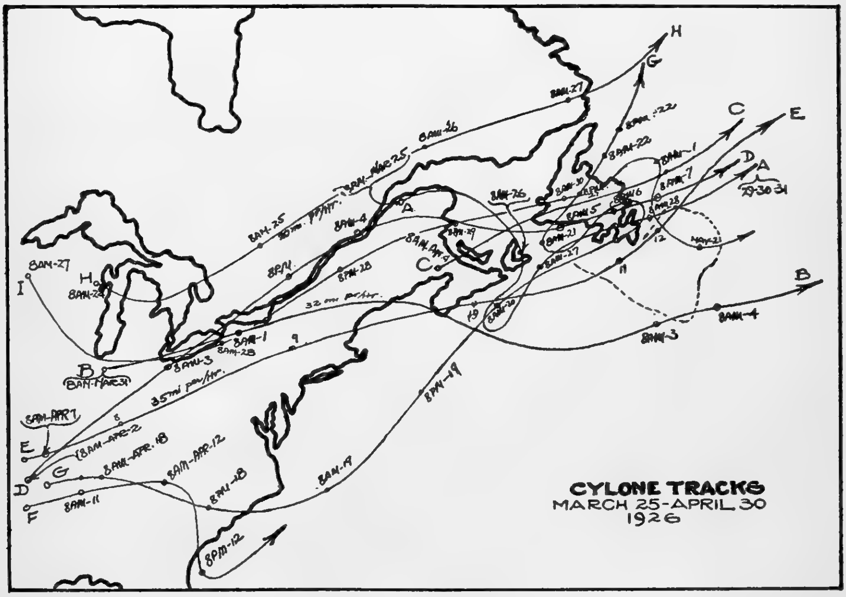

FIG. 5.—March and April cyclone tracks

up the St. Lawrence Valley until it arrived at the upper reaches of the gulf when it curved off to the right keeping over the water as much as possible, and slowly crossed southern Newfoundland on the 5th, 6th, and 7th. It is important to note that this cyclone, similar to several others which have been observed, deepened and intensified as it proceeded up the St. Lawrence River and Gulf. It deepened from a reported pressure in Mississippi of 29.76 to a minimum of 29.28 at Port aux Basque, Newfoundland, and it was at this point approximately 450 miles from the patrol ship that the first effects of the disturbance were felt. The wind shifted to southerly and the barometer fell but as the disturbance began to recede to the eastward it also began to occlude and the winds soon resumed their prevailing northwesterly direction.

While the foregoing storm was raging over Newfoundland another cyclone was growing down in Oklahoma. Its path from April 6 to 12 is lettered E on Figure 5. It followed the mean northeasterly track, as can be seen on the figure, and on the evening of the 11th when 300 miles from the position of the patrol ship it made its first effects felt by the wind increasing to nearly gale force from the south. As the storm moved away out into the North Atlantic we were completely enveloped in an anticyclone which was following on the rear of the "low," and for the next two days we experienced stiff northwesterly gales.

A moderate depression was observed on the meteorological map for 8 a. m., April 10 as centered in eastern Texas. It traveled very slowly in an easterly direction until the 12th when near Atlanta, Ga., it abruptly turned and followed a track almost due south for about 300 miles then reversed itself and moved northeastward. This peculiar behavior was believed due to the presence of an anticyclone of considerable size and intensity to the northward. The disturbance later spread southeastward over the Middle Atlantic States effectually blocking the normal cyclone path.

Track H of a cyclone, April 24 to 27, lay farther north than the other tracks for the month and being so far removed from the Grand Banks region its passing influence could not be detected on the barograph record. Track I, however, the last one for the month, lay up the St. Lawrence Valley so that the center, when it crossed the gulf the night of the 29th, was about 540 miles from the patrol. At this distance it caused our pressure to fall slowly and the winds to shift temporarily from west to east. The rate of travel of this cyclone was about 25 to 30 miles per hour. The month closed with this disturbance central over Newfoundland.

MAY

On May 1 the cyclone that had moved along track I began to drift southeasterly toward the patrol ship and consequently left a graphic record of a sharp bend in our barograph curve for the 2d instant. (See weather diagram for May, fig. 3, p. 35.)

The weather map which we compiled on board the morning of May 2 indicated another depression (29.70) forming to the westward over the Great Lakes region. First it followed an easterly path to the vicinity of Quebec where it hovered until May 3, then curved into northern Vermont and deepened to 29.30. April 4 it passed over the Gulf of St. Lawrence still intense (29.22), yet that evening it suddenly and surprisingly began to fill and by the following day it was very shallow and trough-like. May 6 it was almost squeezed out between two prominent areas of high pressure which merged and for several days prevented the regular procession of depressions which had been in effect prior to this.

It is interesting to observe that the easterly position of cyclone track B on Figure 6, was due without much doubt to the presence of the aforementioned anticyclone. Weather bulletins were received May 5, 6, and 7, containing information that a depression was forming in the region of Bermuda, but due to the lack of ship reports it was impossible to ascertain definitely the movement of the center. During the night of May 8 our barometer began to fall, which from past experience indicated the approach of a storm within a radius of about 500 miles. The next morning upon constructing the weather map the center was revealed near Port aux Basque; it probably had followed a northerly path from Bermuda as indicated on Figure 6. During the next few days the weather maps indicated a tendency of

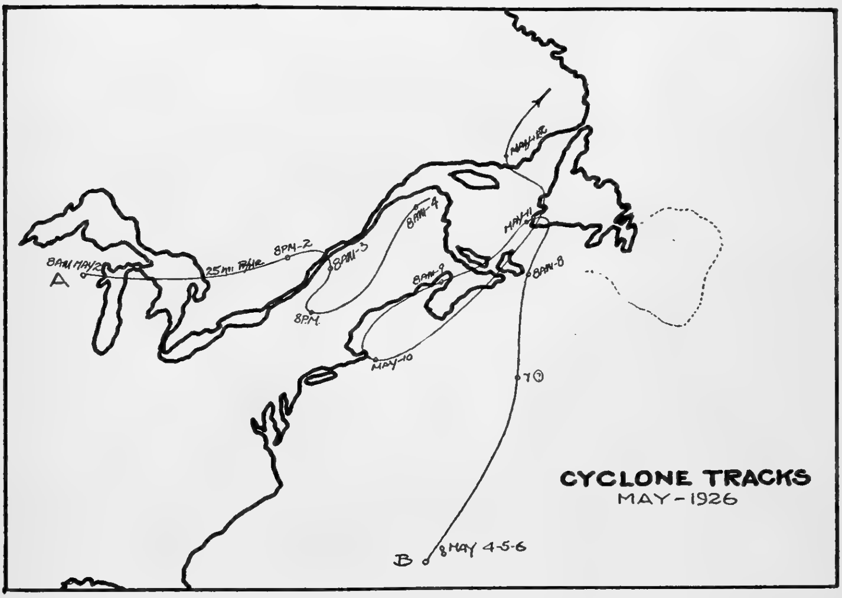

FIG. 6.—May cyclone tracks

the pressure to remain relatively low to the westward, depression centers being recorded from Nantucket to Sydney. On May 11 a deep center appeared near Sydney and moved in a path across the Gulf of St. Lawrence and out to sea. The effects of this distribution set up an indraft of southeasterly winds consisting of warm moisture-laden air pulled across the ice regions from out in the Atlantic. This condition incidently produced the longest period of fog which we experienced for the season.

The two weeks from the 13th to the 27th marked a change in the previously noted tendency of the cyclones to travel consistently along northeasterly tracks Where prior to this period individual centers moved rapidly across the country we now saw several small vortices (families) following meandering paths as if they were the

prey to several factors no one of which exerted outstanding control. For example, on May 13 a slight shallow depression moved from Illinois eastward to the Potomac and the next day spread into a spacious depression with two centers. One traveled eastward while the other remained stationary until two days later it coalesced with a third depression which had been drifting slowly eastward from the Great Lakes. Contemporary with this modification in the weather we noticed that the wind velocities in general had gradually become less than they had been earlier in the season.

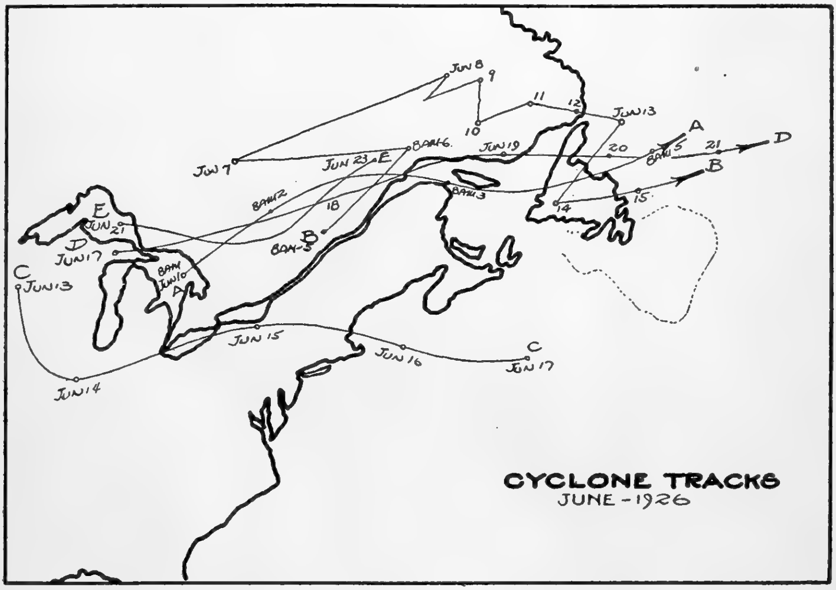

FIG. 7.—June cyclone tracks

May 25 to 30 an anticyclone of vast proportions expanded from the region of central Canada and spread over the entire eastern half of the United States and extended out to include the ice regions. It finally divided into two centers and soon afterward disintegrated completely. It is interesting to examine the flatness of the barograph curve and the presence of clear weather, both of which are recorded on Figure 3, page 35.

JUNE

The most important lesson contained in the cyclone tracks for June (fig. 7) is obtained by comparing the position of the average with the position of the average for the months of March and April. It is clearly indicated that a migration to the northward of the mean cyclone track took place in the course of two months. It is estimated as approximately 150 miles. The explanation for track C, Figure 7,

being much farther south than the others is to be found when reference is made to the daily weather maps. An anticyclone of considerable strength spread southward out of the region north of the St. Lawrence River and probably tended to push cyclone C farther south than it would otherwise have traveled.

The next most striking weather feature in June was the increased number of cyclone families which bred in central North America and persisted in occupying pretty much all of the region northward of a front that extended from the Great Lakes to east of Newfoundland.

PERSISTENCY OF A DEPRESSION IN THE REGION EAST OF NEWFOUNDLAND

Many times during the spring of 1926 we observed that the region immediately east of Newfoundland, and often the Newfoundland area itself, was for days the seat of a deficiency of atmospheric pressure. This persisted so markedly that the phenomenon is regarded not simply as a peculiarity of one season but rather as a general characteristic of all years. As an illustration of the manner in which individual depressions (or a permanent general depression?) may persist in a given region we point to the meteorological maps from 8 a. m. April 15 to 8 a. m. of the 19th during which time the pressure in the Newfoundland theater was constantly lower than that surrounding it to the west and south. The fact that there are observation stations on these three sides of Newfoundland permits one to construct an accurate isobaric map, but it does not throw any information whatsoever on conditions in process in the quarter northeast of Newfoundland. It is easy to see then that we are unable to fix the position of storm centers after they have reached this vicinity, and therefore when we continue to receive reports of low barometer readings from St. Johns it is a natural tendency to conclude the cyclone has paused in its northeasterly progress, but the truth of this opinion is open to question. It may be clearer to regard a series of monthly mean pressure maps of the entire North Atlantic, which over a series of years will reveal the presence of a mammoth depression central near Iceland. It is believed that the continual presence of a depression observed east of Newfoundland on the ice patrol weather maps is in reality the western influence of the great Icelandic minimum accentuated by convergence while crossing Newfoundland of individual North American cyclone centers.

THE STRUCTURE OF A STORM AND ITS PROBABLE PATH

It may be instructive to devote a few very brief remarks to the new ideas in meteorology on the structure of cyclones (storm depressions) and their probable lanes of travel. Forecasters in the past

have usually been guided by the mean cyclone track, as compiled by the statistician, and the barometric tendency gained by simultaneous observations from scattered meteorological stations. Probably some of the most valuable recent contributions to the forecasting art are the investigations of Bjerknes into the structure of cyclones. Detailed analysis of individual cyclones revealed the following two main types of classification:

(*a*) Cyclones which have a definite warm sector separated from the cold part by definite surfaces of discontinuity.

(*b*) Cyclones exhibiting no such individual parts at the surface of the earth.

The former are young intensifying storm centers while the latter are old ones which tend toward retardation in their paths. When they are treated separately a real discovery was made that class A cyclones move in the direction of the air current in the warm sector and very nearly with the same speed as the velocity of the air in that sector. Since the direction of the wind is taken along the isobars, the direction of travel of the storm center shown in Figure 8, page 44, is AB. The isobars in the warm sector are drawn nearly straight because it is found in general practice that they are quite flat. The speed of the cyclone is found by multiplying the distance between the isobars by the sine of the latitude. The whole wind system is in motion and as a rule the direction of the isobar AB in the northern hemisphere will swing anticlockwise and the path of the center O will gradually curve to the left. Sometimes, however, when a small cyclone moves along the edge of a warm anticyclone the change is in the opposite direction. Bjerknes at the Geophysical Institute, Bergen, has found that class B cyclones although not having distinct discontinuity surfaces such as class A exhibit on the earth's surface, do have weather characteristics which correspond to these latter and which do furnish similar information on the career of class B cyclones.

The cyclone is said to be born when two air masses of differing densities come within proximity of each other; the thermal character of the two bodies is the usually accepted index. There follows a period of growth with a corresponding increase in intensity so long as the structure is fed by a sufficient supply of cold and warm currents. Class A cyclones eventually begin to fill up or occlude as the lower limits of the warm sector lift off the earth's surface and shallow out. They are then known as class B cyclones, and the discontinuity surfaces are only to be found at increased heights in the troposphere.

A great number of the storms which affect the ice regions in early season are class A cyclones and it is quite often the case that we are able to observe the passage of the surface of discontinuity in many well-

developed disturbances. The first line of discontinuity to sweep across the observer's position is termed the warm front and this carries along with it the greatest abundance of precipitation. Coincident with the passage of the warm front the winds haul abruptly and also abate in force. The warm sector is characterized by warm moisture-laden air, overcast skies, reduced visibility, less intense winds and occasional rain showers. The second line of discontinuity is called the cold front and squall line. The direction of the wind at this place

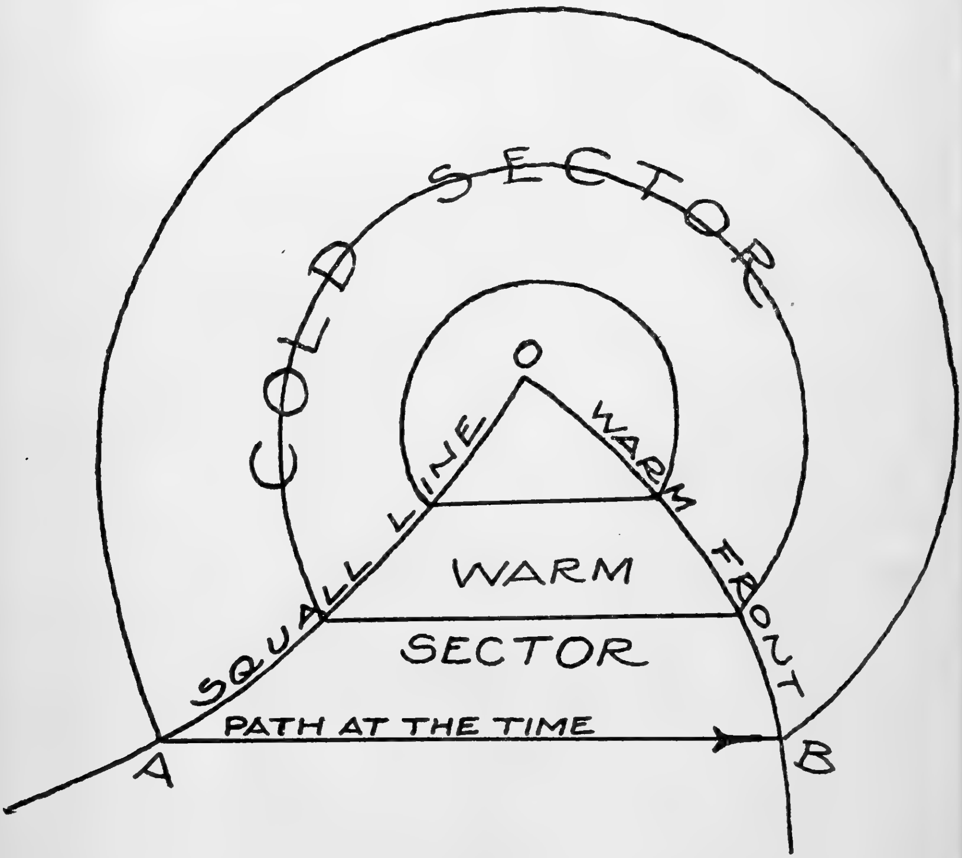

FIG. 8.—The structure of a cyclone

changes quickly to the right, the temperature drops precipitously, and the skies clear. The cold front is often accompanied by rain or hail squalls and perhaps also thunder and lightning and a strengthening of the wind. All of these are interesting to follow: The barograph curve, the wind velocity and direction, the air temperature, and the precipitation during the passage of some of the storms we experience on patrol. Often one can preceive how definitely, even in a crude way, the general structure of a cyclone can be traced.

COOPERATION WITH THE UNITED STATES WEATHER BUREAU

As was done on previous patrols a meteorological map was constructed twice daily on board ship, the data being obtained from the general synoptic reports broadcasted by the United States Weather Bureau from Arlington at 10 a. m. and 10 p. m. In addition to this the patrol ship was furnished with a daily forecast especially prepared by the Weather Bureau. All this information was broadcasted by phone to approaching steamers immediately following the ice broadcasts. The report on fog conditions was one of the most important features of this service from the standpoint of the steamship captain. The element of fog to the Grand Banks region, it is obvious, greatly increases the ever-present danger of collison with ice.

Twice daily, at 8 a. m. and 8 p. m., a weather report was dispatched to the United States Weather Bureau, Washington, D. C., and at the end of each cruise a more detailed report was forwarded by mail to Washington weather officials.

ICE FORECASTING BY MEANS OF THE WEATHER

One of the more important scientific problems that has confronted the ice patrol for some time is the desire to obtain advance information regarding the annual amount of ice to be expected south of Newfoundland. If the master of the *Titanic* had known, as we can clearly see to-day, that the year 1912 was one in which icebergs by the hundreds invaded the North Atlantic to low latitudes, he would probably have navigated his command farther south, and more cautiously, past the Arctic ice barrier. The amount of ice drifting out of the north into the open Atlantic is subject to great annual variations, for instance, in 1912 there were approximately 1,200 bergs counted south of Newfoundland while in 1924 there were only a total of 11. Several investigations[1, 2, 3] have been made of the relation between the amounts of ice in the northeastern North Atlantic and logical contributary factors, but only a few similar papers have dealt with the ice stream past Newfoundland.[4, 5]

All of the investigators, Schott, Mecking, Brenneck, Weisse, and Meinardus found that the wind was the most important factor which governs the southward drift of Polar ice. The ice patrol with the assistance of the British Meteorological Office and more recently, the United States Weather Bureau, has begun an investigation into the

effect of the weather upon the distribution of icebergs. It is desired therefore under this section devoted to weather to give a brief account of the results so far of this research work. The period embraces 47 years, 1880–1926, a series of sufficient length to permit mathematical correlation, and in this respect it has an advantage over previous works.

The results differ somewhat from those previously obtained by Mecking in that the chief importance is assigned to the variations of the pressure difference between Belle Isle, in Newfoundland, and Ivigtut in southern Greenland, during the period December to March. The pressure difference directly affects the amount of field ice, and

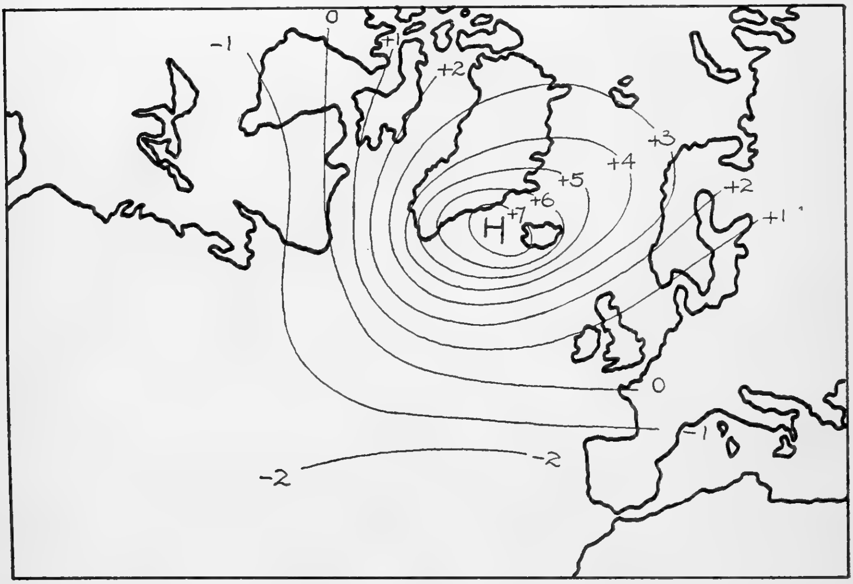

Fig. 8a.—The atmospheric pressure map constructed by averaging the pressures for the months of December to March in the years 1881, 1891, 1895, 1900, 1902, and 1917. These years were all characterized by a lesser amount of Arctic ice drifting into the western North Atlantic than usual. (See fig. 23.)

it has been found that there is a very close relation between the amount of field ice and the number of bergs south of Newfoundland. The field ice tends to act as a fender along the shoreward side of the Labrador current, and thus more or less prevents the bergs from stranding as they are borne southward. The truth of this statement was curiously revealed during the 1924 patrol, when the unusual absence of field ice left the season's crop of bergs to strand in northern waters. When the sea ice recedes northward, due to melting in May, the coast line becomes more and more exposed. Stranding takes place on a great scale, and the consequent supply of bergs to the Grand Banks is cut off. The iceberg menace to steamships in the North Atlantic would be greatly diminished, or prac-

tically disappear, if sea ice did not hamper the North American coast line from February to March every year. The pressure difference between Bergen and Stykkisolm during the period October to January was also found to be of importance.

The use of pressure difference between various points furnishes the best data for forecasting purposes, because there is no room for the personal bias which may come in when charts are classified according to types. A classification of the charts of pressure anomaly over the North Atlantic during the period December to March has, however, been made, and this distinctly reveals two types of pressure distribution—a plus type, in which an excess of pressure

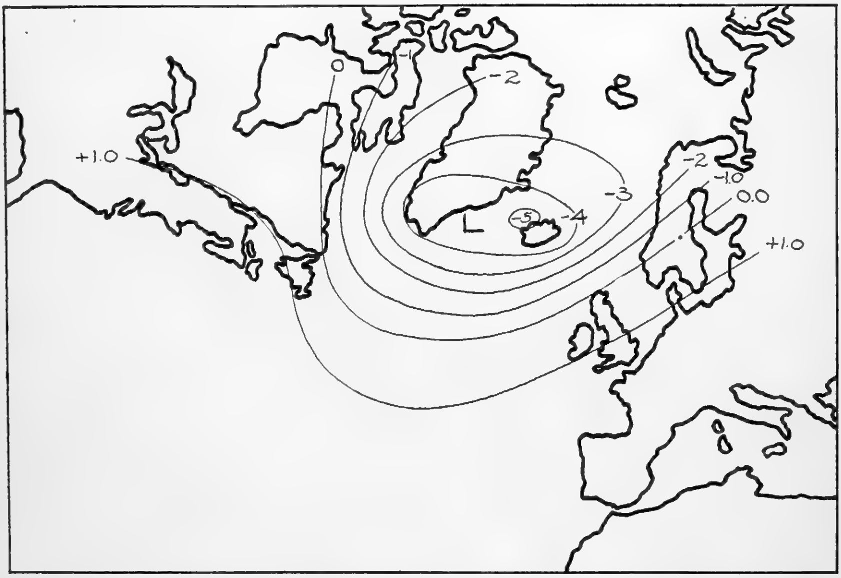

FIG. 8b.—The atmospheric pressure map constructed by averaging the pressures for the months December to March in the years 1885, 1890, 1903, 1912, and 1921. These years are characterized by a greater amount of Arctic ice drifting into the western North Atlantic than usual. (See fig. 23, p. 76.)

centered in the region of Iceland, more or less dominates the Atlantic north of the Azores (see fig. 8a, p. 46), and a minus type when reverse conditions prevail (see fig. 8b, p. 47). The plus type is subject to further classification into (1) and (2), depending upon a relatively great or moderate intensity of the excess pressure mass, both of which are reflected in a relatively very light, or light ice year, respectively, in the western North Atlantic. The minus type, although unmistakably showing a greater amount of ice than normal, does not permit subgrouping. In other words, the plus type of pressure conditions (fig. 8a) exhibit a higher correlation with poor ice years than do the minus type (fig. 8b) with correspondingly rich ice years. This indicates the presence of other factors, such as variations in

the air and water temperatures in the far north, or variations in precipitation, or perhaps an unnatural phenomenon, such as an ice jam in the Arctic Archipelago.

Although the investigation is not yet completed at the present writing, the results already indicate a high degree of success for such a method of ice forecasting. Correlation coefficients have been calculated between the following variables:

(*a*) Number of bergs (on a scale of 0 to 10). (See fig. 23, p. 76.)

(*b*) Amount of field ice (on a scale of 0 to 10).

(*c*) Pressure difference (in millibars) between Belle Isle and Ivigtut, combined with a deviation of pressure from normal at Stykkisholm during the period December to March. The mean pressure difference is calculated from the combination: $2\times$Dec.$+$ $2\times$Jan.$+1\times$Feb.$+1\times$March and this mean is combined with the pressure deviation at Stykkisholm in the proportion of 6 to 1.

(*d*) The pressure difference between Stykkisholm and Bergen during the period October to January, inclusive, December being given double weight.

The correlation coefficients employed in the preparation of the forecast were as follows:

Between (*a*) and (*b*)	+0. 85
Between (*a*) and (*c*)	−0. 58
Between (*a*) and (*d*)	−0. 63

At the end of March a forecast of the number of bergs can be prepared by means of the regression equation:

$$\text{Bergs}=4.8-0.08\ (c)-0.12\ (d)$$

At the end of the field ice season, April 15, the number of bergs, May to July, can be predicted very closely by making use of the high correlation between field ice and bergs.

Arrangements have been made with the United States Weather Bureau whereby that organization furnishes the ice patrol with the pressure data for the months October to March, inclusive, and upon which is based the forecast of bergs for the following spring season. The forecast for the ice season of 1926 was "a light ice year," (3.4 on scale 0–10), while as a matter of record it developed that we experienced very closely to "a normal season 4.3." It is fair to add that we were handicapped in making a forecast due to the absence of pressure data from a very critical area, that of Greenland. This difficulty will probably not arise again as Greenland meteorological stations are now connected with Europe by means of radio.

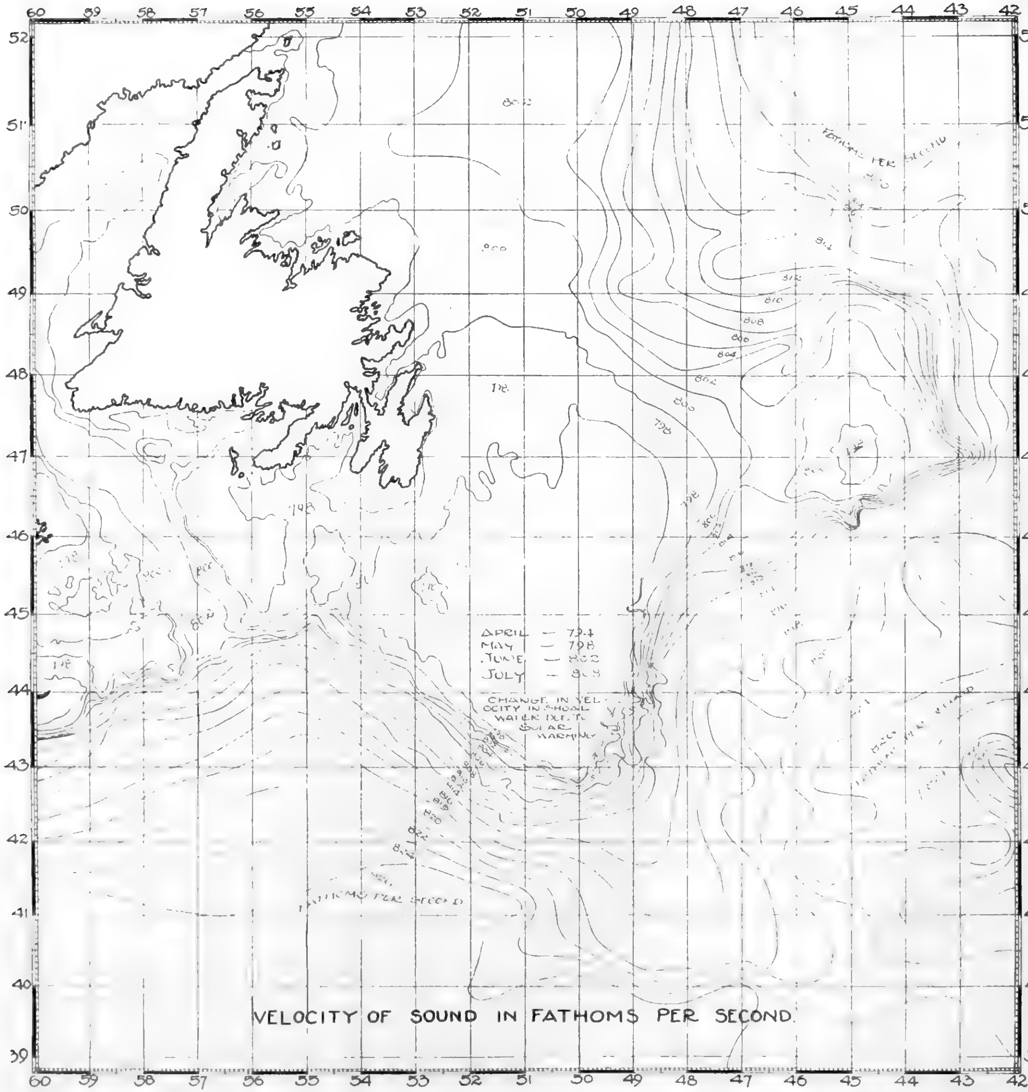

Fig. 9. A chart for use with the sonic depth apparatus showing the velocity of sound in the water column around the Grand Bank

32036—27. (Face p. 49.)

SOUNDINGS CARRIED OUT WITH THE SONIC DEPTH FINDER

As a result of action on the part of the Interdepartmental Board on Ice Patrol at its regular meeting in the early part of 1924 one of the ice patrol ships, the *Tampa,* was equipped with a sonic depth finder of the United States Navy type. The main purpose of the board in having this apparatus installed was to test the practicability of locating icebergs by sonic means. A secondary object was to gain a more accurate knowledge of the bottom contour and consequently of the circulation in the ice regions. An account of the experimental work on icebergs in 1925 and the hydrographical soundings then taken are contained in the report of that year, Bulletin No. 13, page 45. No further work in connection with sound experiments on bergs was attempted in 1926. Arrangements, however, were made whereby a member of the United States Navy sound course at the New London school was detailed to the *Tampa* for the ice patrol. A program was drawn up to take as many soundings as practical to gain further material for a more accurate mapping of the bottom of the ice regions south of Newfoundland than is yet possible, and this work ought to be continued in the years to come. In accordance with the foregoing, a sounding was taken every hour, 8 a. m. to 10 p. m., while the *Tampa* was on duty this year with the result that a total of 465 observations were made.

In connection with this work a chart was constructed (fig. 9, p. 49) to include the ice regions south of Newfoundland showing by zones the velocity of sound after corrections had been made for the influences arising from pressure, temperature, and salinity. The distribution of salinity and temperature in the water mass in the ice regions is quite accurately known from the many oceanographic observations which have been compiled by the ice patrol. The correct velocity of sound in a water column of given temperature, salinity, and pressure is found by reference to very useful tables compiled by Heck and Service. (U. S. Coast and Geodetic Survey, Special Publication, No. 108.) The range of soundings made was from 23.5 fathoms to 2,850 fathoms. The list follows with date, hour, and latitude and longitude.

SOUNDINGS AS RECORDED WITH THE SONIC DEPTH FINDER, 1926

ICE OBSERVATION

Edward H. Smith

When the patrol ship, on her first approach to the ice regions, had arrived in the vicinity of the Grand Bank, a request was dispatched to the Canadian Government Radio Station at Cape Race (VAZ) for a summary of the state of the ice up to date. A detailed reply was received giving the position and character of all the ice that had been reported by passing ships, and this is incorporated in the bulletin for this year, heading the list of ice as contained in Table of ice and other obstructions, 1926 (p. 21). The number of bergs south of the forty-eighth parallel is also recorded by months in the table of iceberg anomalies, 1906–1926 (p. 76). The monthly number has been determined by a compilation of all ice reported by passing ships, as well as that sighted by the patrol, care being taken to avoid listing a berg in this area more than once during any one month.

JANUARY

No ice was reported in the western North Atlantic to the best of our knowledge during January. A normal January reports three bergs south of Newfoundland.

FEBRUARY

The first ice report was reported to Cape Race on February 8 (see Table of ice and other obstructions, p. 21), this being slush ice encountered by a ship on the extreme northern part of the Grand Bank near the 100-fathom curve. Eleven other reports were received at various dates throughout the month, all referring to Arctic field ice on the northeastern part of the Bank, except for one report of several small bergs just south of the forty-eighth parallel on February 20. No doubt these were the remains of one or two large bergs, which had survived the summer of 1925, and, being caught in the fields, were naturally the first of the glacial ice to put in an appearance in 1926. It seems reasonable to conclude that only three bergs came south of the forty-eighth parallel during the month of February. Normal conditions would be 12 bergs during February.

MARCH

Thirty-eight reports were received and distributed throughout the month, of ice in the western North Atlantic south of the forty-eighth parallel. Nearly all of these referred to Arctic field ice or to growlers;

only 13 were of the presence of icebergs. Eight of the latter were of bergs classified as large, and one of these was reported three times. The most dangerous bergs reported during the month were a group of four large and three small, reported three different times, as drifting southward more or less together, from the northwestern part of the Bank. The latest report which was probably the direct cause of inaugurating the ice patrol, was contained in the United States Hydrographic Office broadcast of March 20. This dispatch mentioned the positions of four large and three small bergs in the vicinity of

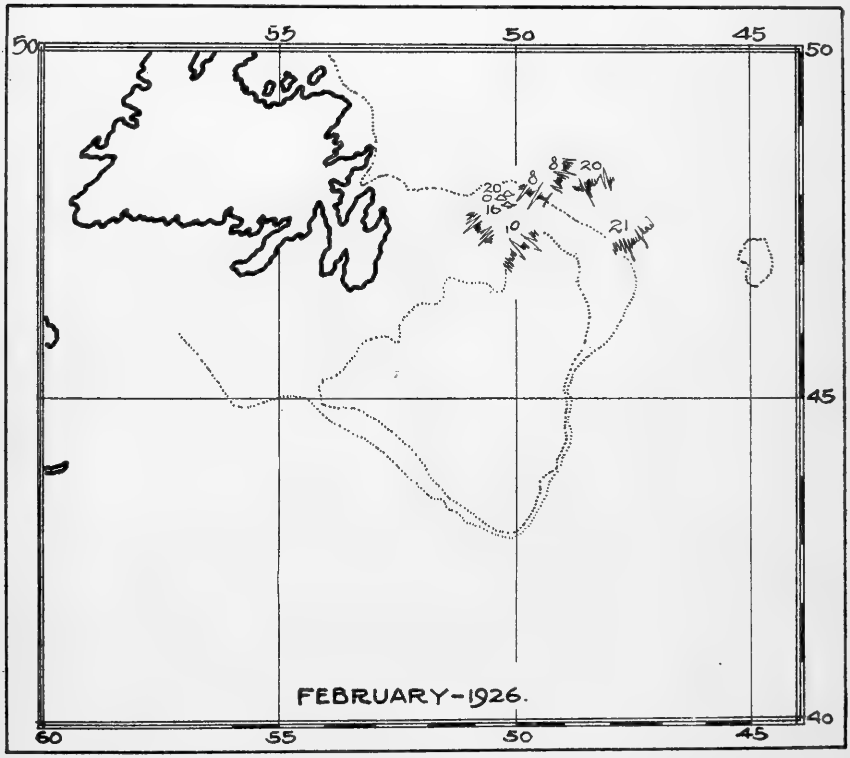

FIG. 10.—February ice map. The position of the first Arctic ice for the season of 1926; the first steamer report from Cape Race was February 8

latitude 45° 15′, longitude 46° 20′. This is about 70 miles offshore of the 100-fathom contour of the Grand Bank, where they might be expected to drift eastward and southward to the northern borders of the Gulf Stream, just where the latter is deflected offshore almost due south of Flemish Cap. No doubt this fate actually befell them as none of these bergs were sighted by the patrol or reported later by passing ships. Probably they finally disintegrated in the warm offshore Atlantic waters, as they drifted northeastward, away from the steamer lanes. Another large berg drifted southward to latitude 45°, about 30 miles seaward of the slope where it was sighted on

March 26. Since no further reports were received, we may conclude that it, too, was caught by the inshore invasion of the warm current and eventually carried offshore to the eastward. It might be added that very few ships frequent the regions where the early season ice is most liable to drift (the patrol at the time is watching the southern end of the field ice), so it is difficult to trace the berg movements in as great detail as is possible a month or two later. Four large bergs were reported on the 27th between the 50 and 100 fathom curves on

FIG. 11.—March ice map. Position and kind of Arctic ice sighted and reported in the western North Atlantic for March, 1926. represents field ice. △ represents an iceberg

the northeastern part of the Bank, this closing the list of bergs reported south of the forty-seventh parallel during the month of March. One of the characteristic drifts of icebergs early in the season (before the early part of April) carries them farther offshore to the eastward than is usual later in the year, as explained in previous annual reports. (See Bulletin No. 12.)

The fact that the first bergs are usually observed relatively far off shore between the Grand Bank and Flemish Cap has been ascribed

to the size and extent of the flat ice both as it tends to prevent the bergs from working in shoreward while they are drifting southward past the coasts of Labrador and Newfoundland, and secondly, because of the prevailing westerly gales which in early season exert a tremendous driving force on the fields, within such packs of which the bergs are more or less bound to be caught and deviated. We confidently reiterate a statement made a year or more ago, "The iceberg menace to steamships in the North Atlantic would be greatly diminished or practically disappear, if sea ice did not hamper the Labrador and Newfoundland shelves from February to April every year." The bergs arriving as they characteristically do between the Bank and the Cap, are borne southward on the northern edge of the Gulf Stream and thenceforth their history is quite consistently to drift off to the northeast, paralleling the steamer tracks and rapidly disintegrating.

Field ice during March was present nearly all the time with its main mass hugging closely to the northeastern sector of the Bank as bounded between the 50 and 100 fathom contours. No field ice, it is worth mentioning, was found inshore of the 50-fathom curve, thus leaving the water over the Banks quite open the entire month. This is decidedly less field ice than usual, for in normal years, during this period, the flat ice spreads out to a considerable area over the Newfoundland shelf. The fields on the eastern side were continually being blown offshore by the prevailing westerlies and just as constantly were they being melted as they drifted out into the deep water off the shelf. Many reports on the seaward side of this ice mentioned the presence of growlers scattered here and there over a considerable frontage. The growlers evidently were nothing more than those parts of the Arctic pans which had become rafted and frozen together, and being of a mass bulkier than the flat ice was able to survive it by a matter of days only. Some of the flat ice succeeded in drifting southward to an extreme point as noted on March 23 in latitude 43° 45′, longitude 48° 07′. Summarizing for the month, we estimate that there were a total of 15 separate and distinct bergs south of the forty-eighth parallel during the period, and this is about one-half the number of bergs that usually drift south during the month of March. The field ice was confined to the northern part of the Banks, along the edge of the slope, and driven southward by the winds to the southerly position as noted on the 23d instant. The amount this year is considered below that present in a normal year, but more than prevailed in either 1924 or 1925.

APRIL

The reports for the month of April began to come in on the second day when a berg was sighted by a ship well to the eastward of the

Banks on the inshore edge of the Gulf Stream. This berg was not reported again, and inasmuch as our records for previous seasons indicate quite consistently that ice in such a position drifts northeastward more or less parallel with the steamer tracks, we felt confident such a history occurred in this case. On the 8th three small

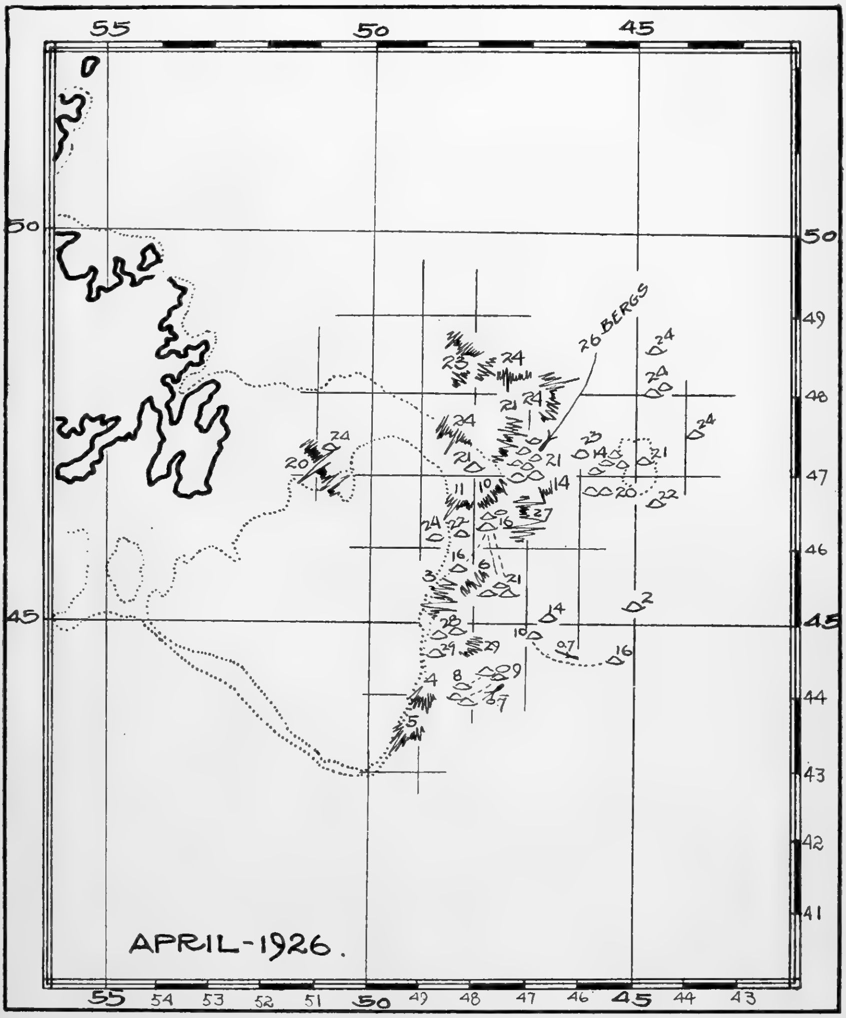

Fig. 12.—April ice map. Position and kind of Arctic ice sighted and reported in the western North Atlantic for April, 1926. represents field ice. △ represents an iceberg

bergs were reported on forty-fourth parallel, 40 miles offshore of the continental shelf and the next day the patrol located this group, it having drifted northeastward at the rate of 0.7 knot per hour. The bergs were really so small that they were nearly the size of growlers and it is believed they became entirely melted by the 12th. This

position on the forty-fourth parallel, it might be added, was the farthest south recorded for any berg during April. Looking northward on the map for April, we note that four bergs were reported the 14th on the western edge of Flemish Cap. Two bergs were just inside the 100-fathom curve to the westward on the Grand Bank and seven bergs were scattered on an east and west line between the Bank and the Cap. A berg was reported on the 16th close in to the Bank slope, and of all the glacial ice recorded to date this berg was regarded from its position as being most liable to drift southward and menace the southern routes. This fear proved groundless as nothing more was heard of its career. A berg was reported offshore on the 10th, and again on the 14th, in each instance located without much doubt in the northern edge of the Gulf Stream drift. A second report from this locality of a small berg probably referred to the one previously mentioned on the 10th; its new position would accord with the oceanographic circulation and indicated a rate of drift of 0.7 knot per hour. Three bergs between the forty-fifth and forty-sixth parallels about 50 miles eastward of the slope were reported on the 21st and it is believed that they were the same as two previously recorded on the 16th, which would account for a drift almost due south at the rate of 0.4 knot per hour.

Clear weather set in the 22d on the northern routes and for a period of the next three or four days a considerable number of bergs were reported which greatly augumented the list for April. For example the most populous distribution existed on the 100-fathom curve in latitude 47° where one ship sighted 26 bergs and an extensive ice field. These bergs with the addition of a few scattered ones were continually being reported by passing vessels the 23d to 26th instant. On the 28th and 29th three or four bergs of this aforementioned original group were reported south to the extreme limit for the month, excepting three small bergs on the 8th, on the east edge of the Bank in latitude 44° 45′. One berg only was reported in on the shelf, but its position was well to the northward in latitude 47° 20′ longitude 50° 45′. It is worth remarking that records show only about one-eighth or one-ninth of the total number of bergs south of Newfoundland ever succeed in drifting south of the Tail of the Grand Bank.

We ought not to fail to mention the behavior and distribution of the field ice for April. It was present during the entire month on the northeastern slope of the Banks north of the forty-sixth parallel, but due to the fact that there were few ships passing through this zone the presence of the fields were not recorded often. Whenever a ship crossed this vicinity, however, we were quite certain to receive an ice report. The patrol recorded what proved to be the southernmost invasion of the Arctic sea ice for the current year, the field

being sighted in the form of an attenuated tongue stretched southward along the edge of the slope to latitude 43° 23′ on April 5. Its movement between the 4th and 5th was at the rate of 1 knot per hour parallel to the slope, while three days after, during the interim of which a westerly gale had prevailed, no vestiges were to be found except an occasional growler here and there well offshore of the slope. On the 29th we received a report from the master of the sealing steamer *Terra Nova* (Captain Kean), containing a general account of field ice conditions northward along the east coast of Newfoundland. He stated having found the main pack about 40 miles north of Funk Island in the early part of March where also were loacted the seals. Northerly winds prevailed, driving the ice into the rivers and bays along the coast, more or less blocking the entire coast line southward to Bonavista Bay. Captain Kean had completed the catch by the 20th and was leaving the western edge of the pack, then about 100 miles east-northeast of Cape Race. The field ice this year, he stated, was much nearer land than last year and there did not appear to be a great quantity of bergs. Field ice was reported off and on pretty nearly throughout the entire month's span and its eastern limits, to the northward, coincided very closely with the forty-seventh meridian. The last few days of the month (the 28th and 29th), field ice emerged again southward to within 80 miles of its farthest southern point described April 5. On April 29 a patch was reported in latitude 44° 30′, longitude 48°.

Summarizing for the month we estimate that there were a total of 58 bergs south of the forty-eighth parallel, the normal number being 78; this is approximately 33 per cent less than the average.

MAY

The reader will recall that during April a group of three bergs had been reported in an extreme southerly position on the east side of the Banks, latitude 44°, on the 8th instant. No bergs had been reported so far south as this throughout the month until the last few days, the 28th and 29th, when a group of three bergs were sighted by a passing steamer between the forty-fourth and forty-fifth parallels in the deep water just off the slope. The first report for the month of May, which indicated that the bergs were on the move to the southward, was that of the 2d instant when a berg was sighted in latitude 44° 10′ on the east side of the Banks. The patrol ship at the time was a few miles southeast, hove to in a northwesterly gale but the position of this berg was regarded with considerable interest as it was the second one for the year, apparently, which was in a critical position to drift southward of the Tail. Accordingly as soon as the gale abated we commenced efforts to locate it and so on from the 3d to 11th instant we carried on a search estimating the probable drift from day

to day. The work, however, was greatly handicapped by continual encounters with fog and low visibility which no doubt prevented the patrol from making contact with this iceberg. Throughout this period of eight days reports of bergs to the northward were continually being received and also information regarding the position of isolated fields of ice on the eastern side of the Bank, but none southward of the forty-sixth parallel. Other patches of field ice were reported between

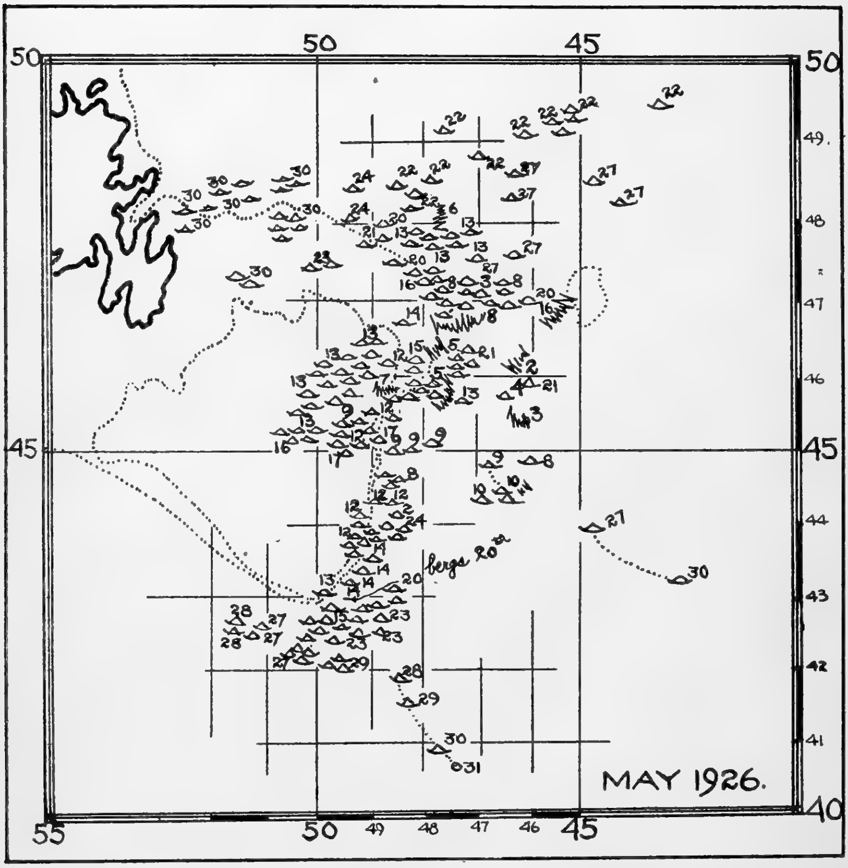

FIG. 13.—May ice map. Position and kind of Arctic ice sighted and reported in the western North Atlantic for the month of May, 1926

the Grand Banks and Flemish Cap. On the 5th, 8th, 9th, and 12th days in May bergs were reported in groups as large as three to five in number all the way from the forty-fifth parallel southward to latitude 43° 30′ just eastward of the edge of the Bank. The reports were not in great detail on account of fog enveloping this entire area, but it was not difficult to observe in general that the bergs were commencing to get farther south and were drifting in their usual path toward the Tail of the Bank. A respite from foggy weather came at last on

May 13 and 14, and these two days of excellent visibility permitted the patrol ship to locate a total of 21 bergs which were scattered along the eastern side of the Bank from the forty-third parallel northward to latitude 44° 15′. This was really the first period of serious scouting

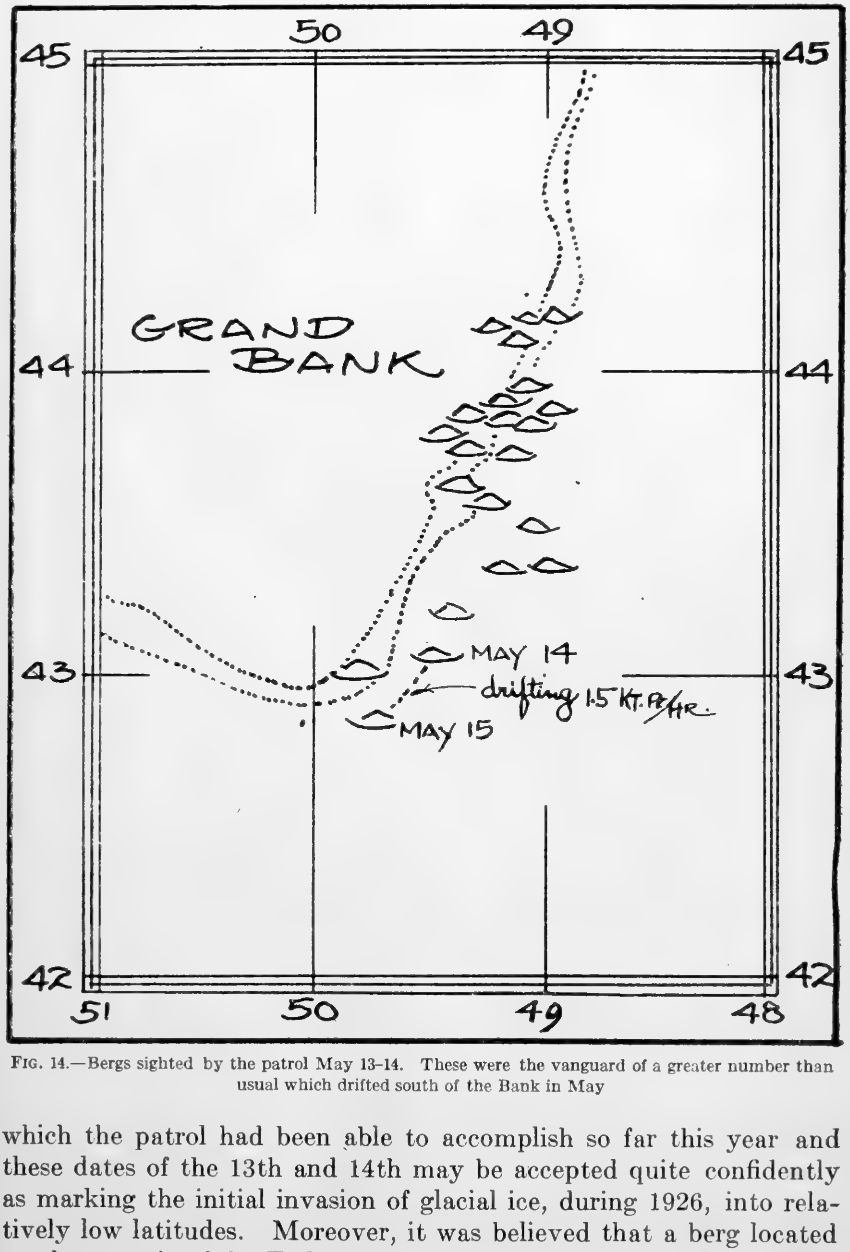

FIG. 14.—Bergs sighted by the patrol May 13–14. These were the vanguard of a greater number than usual which drifted south of the Bank in May

which the patrol had been able to accomplish so far this year and these dates of the 13th and 14th may be accepted quite confidently as marking the initial invasion of glacial ice, during 1926, into relatively low latitudes. Moreover, it was believed that a berg located on the very tip of the Tail of the Bank on both of these dates, was one

and the same as reported in a dispatch of the 22d instant and as previously discussed. It remained grounded in this spot; depth of water 43 fathoms, for the next four or five days.

The clearing of the fog on the 13th and 14th instant was due to the northward spread of the summer time North Atlantic high pressure area, which accordingly caused a shift of the wind from the prevailing southerly direction to the northwest quadrant. Not only was this clear weather a great boon to the patrol, enabling it to accurately fix the position of the southerly bergs, but also it permitted steamships to the northward which were crossing the continental slope, east and west bound from Canadian ports, to sight numerous bergs in those regions. There was a total of approximately 102 reports concerning the position of bergs north of the forty-fifth parallel submitted by passing steamers to the patrol vessel in order that we might collect and rebroadcast such information to other ships. In fact, during this period of nine days there were received about two-thirds of the reports for the entire month, all of which concerned the location of bergs distributed from the forty-fifth parallel northward to the forty-eighth parallel. The area containing the most abundant amount of ice was between the forty-sixth and forty-eighth parallels on the eastern side of the Bank. Nearly all the aforementioned ships were using track E, and the distribution of bergs as shown from the map indicated this populous belt extended northeast and southwest from just inshore of Flemish Cap southwestward in over the Bank to an extremely western position of longitude 50° 20′.

The duration of clear weather was comparatively short, for on the 15th instant about noon the fog shut in again with earnestness. This illustrates the general behavior of weather conditions during the spring of the year and with which the patrol is obliged to contend. Prevailing atmospheric circulation supplies a more or less constant indraft of warm moisture-laden winds which blow from the southerly quarter and the Gulf Stream. These winds, reaching the relatively cold water which surrounds the Banks, are cooled and their moisture is precipitated mostly in the form of fog interspersed with rain. Occasional interruptions come in the form of high-pressure atmosphere phenomena which usually bring clear weather for a short time only, so that the patrol has come to expect on the average a period of four to seven days of thick weather followed by two or three days of clear visibility and then a resumption of fog. Before the fog rolled in on the 15th the patrol vessel had time to identify one of the southerly bergs as observed the day previously which was then drifting 1.5 knots per hour southwestward past the Tail. Here then was a potential menace which was probably drifting to the westward, and from the current map probably on to the southwest slope;

but a small deviation in the current might tend to transport this ice offshore, where it was liable to be turned to the eastward and eventually appear in a very unsavory position immediately northward of the steamer lanes. The current map, which had been compiled on board April 29 to May 5 (fig. 49, p. 109), about two weeks previously, indicated, however, that the probable tendency for this ice was inshore to ground on the Bank.

Fog, as we have just remarked left nothing else for us to do but wait patiently near the Tail of the Bank and somewhat to the southward, blind to the movement of the 21 bergs, but hoping any day to get an opportunity for clear weather and another search. The fog continued to prevail for five days, but on the expiration of the third, we decided to remain inactive no longer. It was thought that failing to follow this ice by means of actual contact each day, the next best proposition lay in compiling on board, as soon as possible, a map showing the current in this critical region which was now infested with several bergs. The ice patrol ship, therefore, May 18 to 20, was occupied in making a current survey of these fog-bound waters south and southwest of the Tail—the so-called critical area.

The fog cleared on the 20th instant and also the same day the oceanographic work was completed and the course and velocity of the currents were mapped. As a result of this work is discussed under the section of oceanography it will not be mentioned in detail here except to remark that the Labrador current flowed westward from the Tail to latitude 42° 34′, longitude 51°, and from this point one branch swept westward flooding the slope of the Bank, while offshore a branch bent sharply back 113° through latitude 41° 55′, longitude 50°. A natural inquiry for the reader to make is, "What was the subsequent behavior of the large group of 21 bergs which was located just north of the Tail on May 14?" Since none of this ice was sighted in the critical area southwest of the Tail during the oceanographic survey, it is believed several of the bergs were detained around the slopes of the Bank, and that most of them drifted offshore into the northeast set, with practically no ice following tracks southward past the Tail. It is most likely that the inshore edge of the warm counter current which we have just described on the current map, transported the majority of these bergs northeastward finally to melt them away from the steamer lanes. It is unfortunate that the patrol ship had no opportunity during the month to search this locality in order to corroborate such a belief.

During the period May 15 to 20, reports from ships traversing the regions to the northward were not so numerous as earlier in the month yet it ought to be remembered that these waters were en-

shrouded in fog as well as where the patrol ship was further south. In spite of the low visibility on the northern routes, however, the bergs continued to be reported, which is pretty good evidence that they must have been quite plentiful, and many of the reports mentioned passing ice close aboard.

Just about nightfall on the 20th of May the steamship *Tiger* reported the position of 10 icebergs to the patrol, on the forty-third parallel, and about 25 miles east of the Tail. The patrol at the time was only a short distance to the southward finishing the last of the oceanographic stations and inasmuch as this ice was in a position from which it was liable to drift farther south the patrol laid plans to locate these bergs the next morning. Fortunately the 21st, 22d, and 23d of May were days of clear weather and this permitted us to determine the position of 26 bergs distributed around the Tail and as far north as 43° 20′. The distribution of this group is shown on the accompanying sketch. There were no large bergs found and it was quite striking to observe that they were all about the same size and fairly well collected together. It is also worth remarking that none of these bergs were identified as any of the former group sighted on the 13th and 14th instant, nor would such a coincidence agree at all with the set and velocity of the currents which had been flowing in this interim of about one week. Several of the bergs were carefully watched as to geographical position and it was quite plainly observed that those farther offshore of the slope were being turned or retarded in the dead water which from the current map existed there. This movement is further illustrated on Figure 15, page 65. A regard of the current map together with the positions of the bergs convinced patrol officials that this ice constituted a serious menace to the present North Atlantic lane routes and it was believed that within the space of 7 to 10 days many of the bergs would be on, or uncomfortably near, the steamship tracks. It was deemed of utmost importance, with such information at hand, to advise Washington immediately to shift the tracks farther south.

Reports regarding the position of bergs to the northward continued to be received by the patrol, and after May 15 the shift from track E to Cape Race track, caused numerous bergs to be sighted in the more northerly latitudes of 48° and 49° and also longitudes farther west, viz, 50° and 51°. (See fig. 13, p. 60.)

The patrol was engaged in effecting the relief between its two ships the 24th and 25th and on the 26th instant, when we had returned to the vicinity of the southern bergs, south of the Tail (see fig. 15, p. 65) a dense fog was encountered. A steamer passing close to us on this day reported having narrowly missed a berg and growler, and a brief light up during the afternoon permitted us to sight what was believed to be the southernmost ice. It was foggy at this time, it must

be remembered, and no great area could be searched nor could the bergs be definitely located, so under such conditions there was bound naturally to be a feeling (realizing as we did the direction and velocity of the current), that there was a very good possibility of scattered bergs drifting in widely distant positions. The problem seemed to be without solution, however, as long as fog continued to envelop these waters. Clear weather came on the 27th instant and the patrol was able to get in touch with some of the bergs of the group last plotted in positions May 21 to 23. (See fig. 15.) A group of five bergs were kept in sight for two days, the 27th and 28th instants, and were subsequently reported by passing steamers on

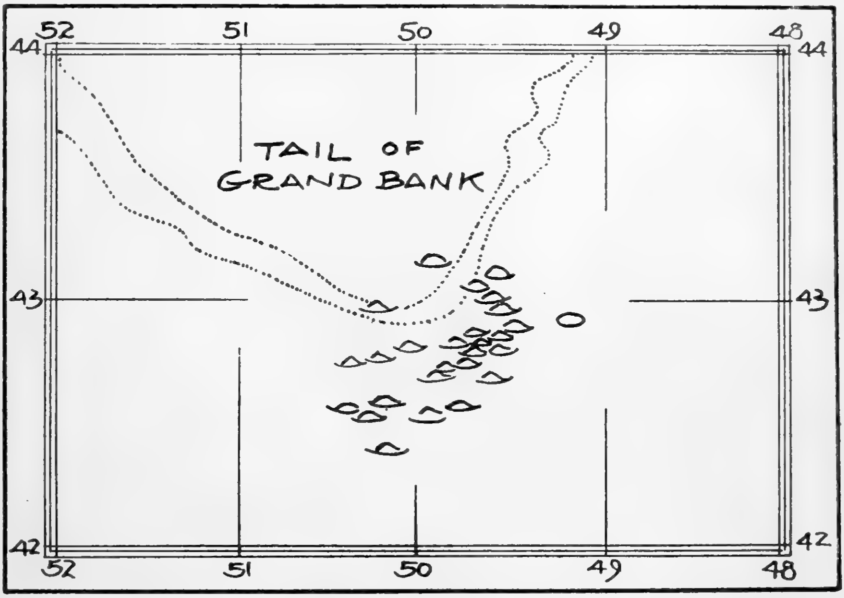

FIG. 15.—Bergs sighted by the patrol May 22 and 23. This was not the same group located May 13–14. (See fig. 14, p. 61.)

May 29, June 1, 2, and 3. Figure 16 is inserted on page 66 in order that the reader may follow the relative positions and career of this ice. The northern bergs of the group were, according to the current map, on the inshore edge of the offshore current but the three southern bergs, that is, those farthest offshore, were in the current proper, drifting 100° at rate of 0.5 knot per hour. This agreed very well with the current as calculated there May 18 to 20, and it showed, furthermore, the manner in which the offshore bergs in the stronger current outdistanced those only a matter of 5 miles or so farther inshore.

Here is an excellent example of the appreciable difference possible in the movement of the water between two places located relatively

close together in this critical area south of the Tail. While we were lying near the bergs on the 28th instant observing their behavior, a report of a berg in latitude 41° 50′, longitude 48° 23′ was received and this being only 20 miles north of the westbound track and also the southernmost ice, the patrol immediately headed toward the position at full speed. Twice during the afternoon the same ice was reported by other vessels in about the same position at which we arrived near nightfall. The berg was not very large and was thought to be one of that group originally sighted on May 14 just north of the Tail for its position could under such conditions be attributed to the course and velocity of the current. We followed this berg for three days, the 29th, 30th, and the 31st (see fig. 17, p. 67), and inasmuch as it was unusually far south position for ice, during these three days of disintegration it merits more than passing interest.

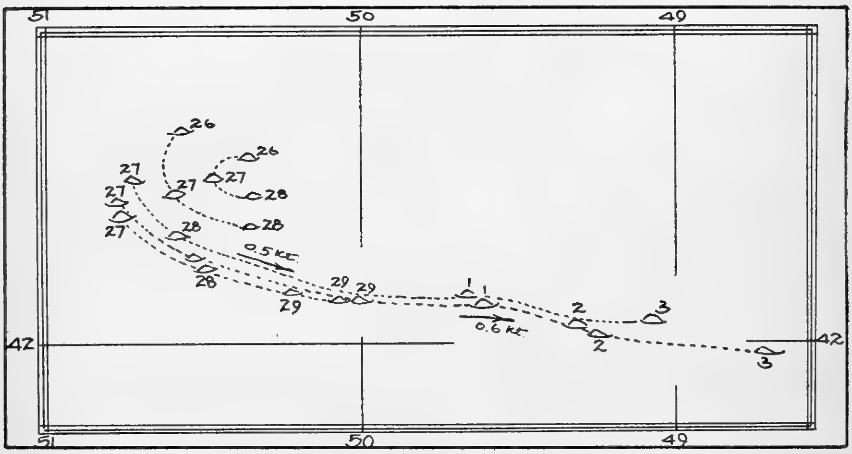

FIG. 16.—The behavior of a group of five bergs May 26 to June 3, drifting on the northern edge of the Gulf Stream south of the Grand Bank

At 5.30 a. m. on the 29th we sighted the berg bearing 210°, distance 4 miles, and approached nearby. It was approximately 150 feet long and 60 feet high. A light sea was running from the northeast, the sky was overcast the entire day, and the temperature of the water was 46°, with the air 47°. We fired 18 to 20 shots with the 6-pounder after gun which brought down considerable ice. In the afternoon two mines containing about 238 pounds of T. N. T. were exploded beneath the surface while suspended by a rope from the berg. The mines tore off several large growlers, but did not cause any great amount of damage. On May 30 during the 4 to 8 a. m. watch a northeasterly swell began to make up which continued quite "lumpy" all day. We came up close to the berg about 2.45 in the afternoon and it was apparent to everyone on board that it had been reduced to one-half its size of yesterday. Many growlers were calving off

and the rate of disintegration was rapid. The sea-water temperature did not change from that of the 29th until about 8 o'clock in the afternoon when it rose to 55° as we drifted across the "cold wall." The sky was overcast similar to that of the preceding day. Constant

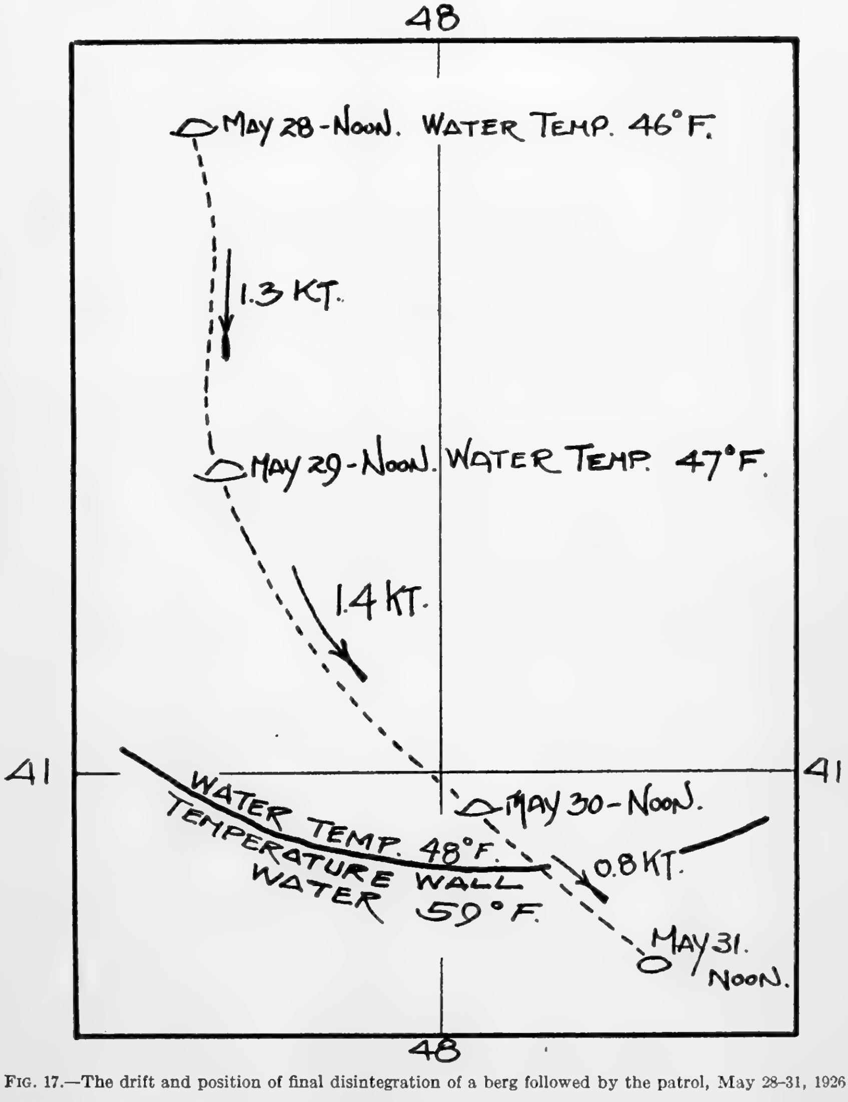

FIG. 17.—The drift and position of final disintegration of a berg followed by the patrol, May 28–31, 1926

touch was kept with the berg during the night and on May 31, at 8 o'clock in the morning, it was no larger than a good size ship's boat. The water temperature had remained constant and the northeast swell continued. The rapid rate of disintegration described herewith is attributable mainly to the appreciable swell and sea which in the

24 hours entirely effaced the berg as a menace to navigation. This is one of the most rapid cases of disintegration of which the patrol has an account and it brings out one fact quite forcibly, namely, that bergs which attain extremely far south drifts such as near the Azores Islands or near the British Isles can only be accomplished when the berg is floating in a comparatively calm sea.

A summary for the month indicated the following outstanding features: Field ice was not reported south of Newfoundland after the 6th of May. There was this month, however, a great increase over April in the number of bergs reported in the northwestern North Atlantic. The first group of bergs, 21 in number, to arrive at the Tail of the Grand Bank (the gateway to the Atlantic), were sighted by the patrol on the 13th and 14th instant. A great increase in the number occurred during these few days of clear weather when ships on northern routes were also able to sight them. Fog enshrouded the regions from the 15th to 21st but the latter day of which we had a clearing and 26 more bergs were found around the Tail. These it appears quite safe to state were not the same as those sighted the 13th and 14th instants. The 15th to 24th many more bergs sighted between the forty-eighth and forty-ninth parallels by ships which now had commenced to use the Cape Race tracks. May 22 to 31 the patrol kept in touch with the southern and eastern fringe of ice and tracked "strays" to extremely low latitudes, across the west-bound steamer lane.

It is difficult to estimate the number of icebergs south of Newfoundland during the month of May due to the great duplication of reports, but to the best of our belief we state that there were a total of 168, which is 10 per cent more than normal. As for the area south of the Grand Banks we estimate a total of 36 bergs, which is 100 per cent more than normal. This is a great increase in numbers over what was in these regions at any time earlier this year or during any part of 1925 or 1924. The sudden and great increase in numbers, which came with a rush during the month of May, is more or less in agreement with the general character of the atmospheric circulation which prevailed December to March, 1925–26. Conditions were unfavorable towards a normal distribution of ice from October to January, but from January onward atmospheric conditions changed to a diametrically opposite character, which undoubtedly is reflected in a correspondingly sudden increase in numbers of bergs around the Grand Banks for May.

JUNE

The preceding month, May, indicated a total of 168 bergs south of Newfoundland, and 36 south of the Tail of the Bank. The latter figure is twice the normal number and consequently the patrol looked forward with no small amount of conviction that an abnormal num-

ber of bergs would probably continue during June just northward of the steamer tracks.

The first five days were spent following and standing by two bergs both of which drifted across the westbound tracks between meridians 48 and 49, and consequently formed a distinct menace to steamships during this period.

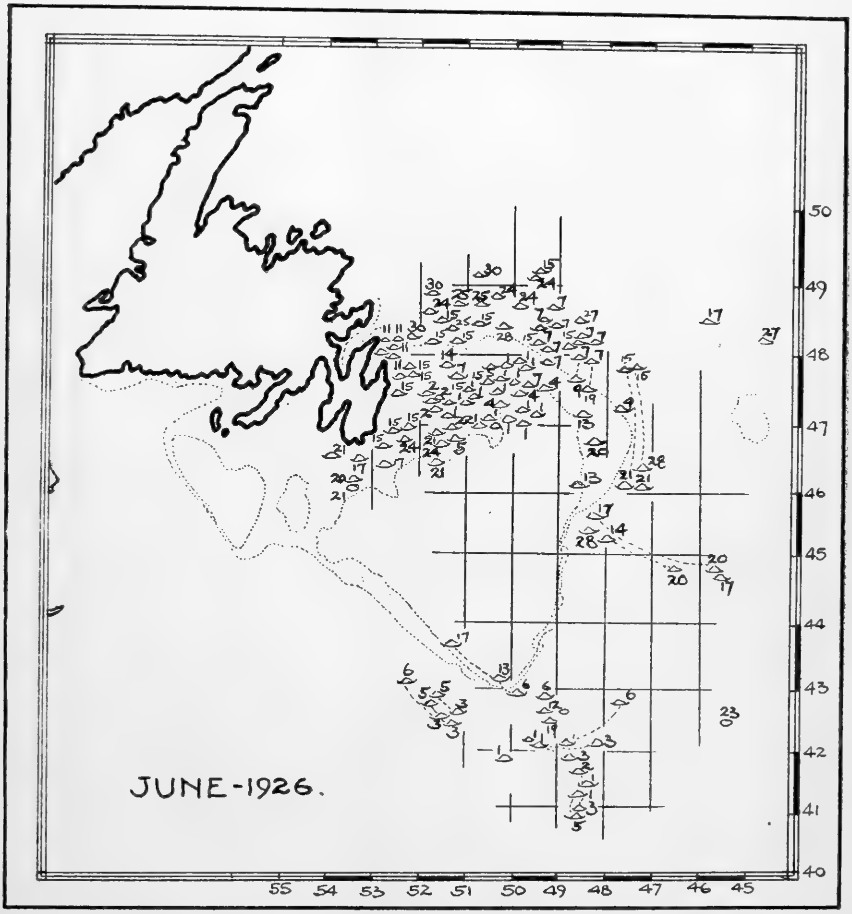

FIG. 18.—June ice map. Position and kind of Arctic ice sighted and reported in the western North Atlantic for June, 1926

The sketch shown herewith gives a good idea of the rate and direction of their drift. It is a drift which is noteworthy for the fact that it lies almost at right angles to the general direction of the Gulf Stream (or what we have conceived or believed to be the prevailing direction of flow) in that particular region. Three oceanographic stations taken somewhat to the northward during the period covered, June 1 to 5, indicated no appreciable set, at least in no way com-

mensurate with the drift rate of the ice, viz., 1 to 1.4 knots per hour If we compare the behavior of these two bergs as to their progressive movement southward between the forty-eighth and forty-ninth meridians, with a distribution of icebergs south of Newfoundland 1900–1926 (see fig. 25), we immediately note the tendency of the ice to attain an extremely far south position takes place between these two meridians of longitudes almost without exception. On June 4 two boats were lowered from the *Tampa* and directed to wire drag berg B, in order that data might be compiled by the ice patrol regarding the draft, volume, etc., characteristic of Arctic icebergs. At

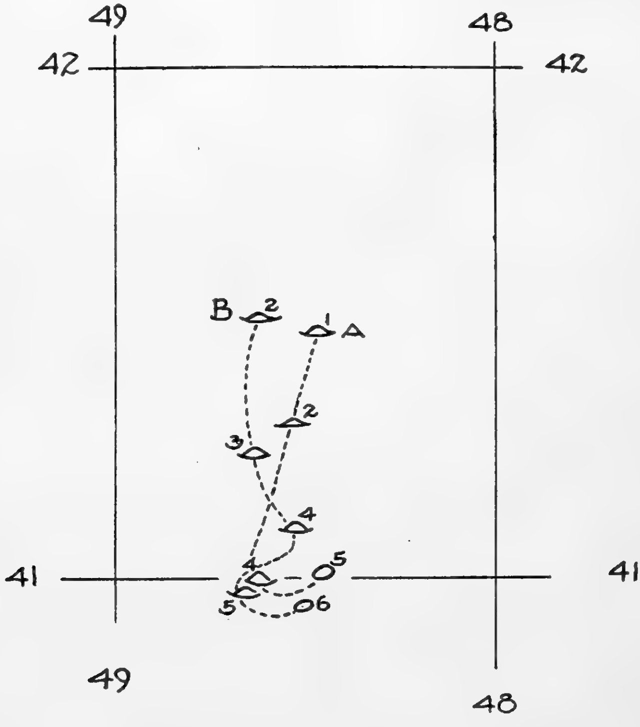

FIG. 19.—The drift of bergs A and B across the westbound steamship lanes June 1 to 6, 1926, inclusive

the same time that the small boats were working on this job measurements as to the exposed surface of the ice were made on the *Tampa* by means of sextant and range finder. The wire dragging operations, unfortunately, were unsuccessful due to the parting of the span which consisted of a condemned sounding machine wire. The above water dimensions were found, however, to be 382 feet long, and an average height above water of 42 feet. This was at 4 p. m. on June 4, latitude 41° 06.5′ north, longitude 48° 27′ west. At 6 p. m. a large square tower on the right-hand side of the berg fell off causing that end to rise, setting up new strains which resulted in cleaving the berg

sharply in twain. The face of the cleavage was as flat as if had been carefully planed to such a surface. Naturally, this increased tremendously the rate of disintegration. The temperture of the water and the state of the sea and weather remained quite the same (see p. 36) for the next five days as that recorded on June 4. At 6 p. m. June 5, 24 hours after the disruption described above, the growler formed by the tower sliding into the sea, had entirely disappeared because of melting. The two small bergs formed June 4 were by the 5th a small berg and a growler in size. At 4 a. m. June 6, latitude 40° 56′, longitude 48° 33′, only 10 hours later, every bit of ice had melted. If we had not actually observed this with careful note, we would have been quite skeptical, I am sure. Such an enormous mass of ice such as we measured on June 4 completely disappearing is hard to reconcile with such an extraordinary survival as recorded of a piece of ice June 25 sighted in latitude 30° 20′ north, longitude 62° 32′ west (see U. S. Hydrographic Office Weekly Bulletin for December 8, 1926.)

The ice regions north of the temperature wall on June 4, which had enjoyed clear weather since May 28, were blanketed in fog which prevailed over these waters until June 13, a period of eight days. After remaining near bergs A and B (see fig. 19) until they had completely melted, the natural procedure was to scout and get in touch with other bergs of the group of 26 seen south of the Tail, May 22 and 23. These bergs, being in the colder waters north of the temperature wall, was thought to be in various, but less menacing positions in this region. We attempted scouting but were rebuffed by the fog pall from June 6 to 13. When we did search these waters (the 14th to 17th instant) northward along the east side of the Bank to the forty-fifth parallel no ice was to be found. Passing steamers located a group of three bergs west-southwest of the Tail which from several consecutive reports indicated they were drifting northwest in a branch of the inshore current, up on to the southwest slope of the Bank. A small piece of ice was reported on the 12th and again on the 19th, not far offshore southwest of the Tail in the dead water, and another berg was seen on the tip of the Tail on the 13th and farther northwest on the Bank on the 17th. This was the last report of ice in the region of the Tail for June, so one can appreciate with what suddenness the relatively large group of bergs in positions south of the Tail disappeared from these waters during this month.

Bergs on the northern part of the Bank, on the contrary, continued to be reported with little abatement during the entire month. There were many reports which referred to the same bergs, this fact being quite apparent to anyone charged with keeping a careful check on the total number of bergs. The tendency of drift of these bergs was quite in accordance with what has been observed in previous years, namely, to ground and drag along the bottom and break up

on the northern slopes of the Grand Bank. Then as the season grew older, the latter part of the month, an increasing number of bergs were reported in positions along the east coast of Newfoundland, and in the deep-water gully which leads around Cape Race. Such a tendency as described is well shown on Figure 18, as is also the comparatively large number of bergs which collected and stranded on the northern part of the Bank. A report from the steamship *Empress of France* on June 30 indicated a decrease in numbers even here.

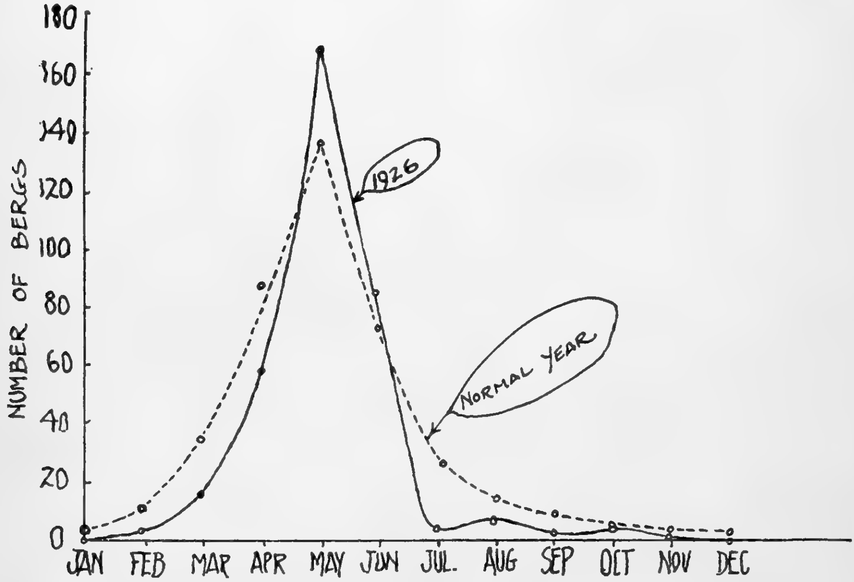

FIG. 20.—Distribution of icebergs south of Newfoundland, 1926. The full black curved line represents the actual distribution, while the dotted line is the normal distribution

The absence of berg reports between parallels 43 and 46 on the eastern side of the Grand Bank was quite noticeable if we but glance at Figure 18. The three or four which were sighted in this locality drifted eastward on the inner edge of the Gulf Stream and did not get south of the Tail. The underlying cause for such a dispersal is contained in a current map especially compiled by the *Tampa* just prior to the discontinuance of the patrol on the 30th instant.

Summarizing, we state that there was a total of 85 bergs south of the forty-eighth parallel, about 10 per cent more than normal, and of this number there were 12 south of the Tail of the Grand Bank, all for the month of June. The most outstanding feature was the rapid decrease in numbers of bergs drifting southward of Newfoundland during June. The waters, after the 17th instant, were entirely free of bergs that could possibly, from currents, and experience

of previous years, drift southward and jeopardize trans-Atlantic navigation.

The distribution of icebergs south of Newfoundland by months during 1926 was:

January	0	April	58	July	4	October	3
February	3	May	168	August	6	November	1
March	15	June	85	September	2	December	0

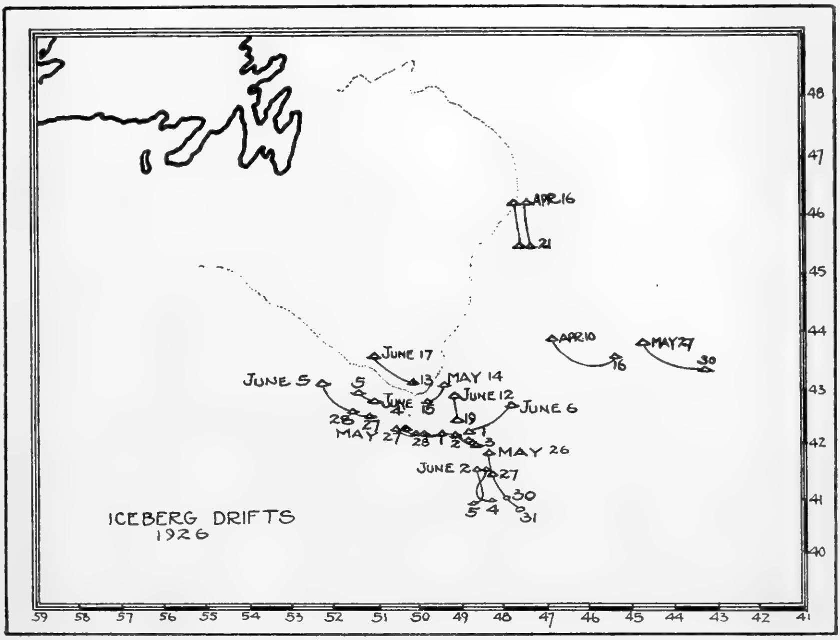

FIG. 21.—Iceberg drifts recorded during the season of 1926

This is shown graphically by a full black line, Figure 20, page 72. The normal distribution is shown as a dotted line.

The bergs that the patrol were able to track in drifts during the ice season are recorded on Figure 21.

A compilation has been made of all the drifts of icebergs around the Grand Bank that the ice patrol has been able to follow, and this chart is shown here.

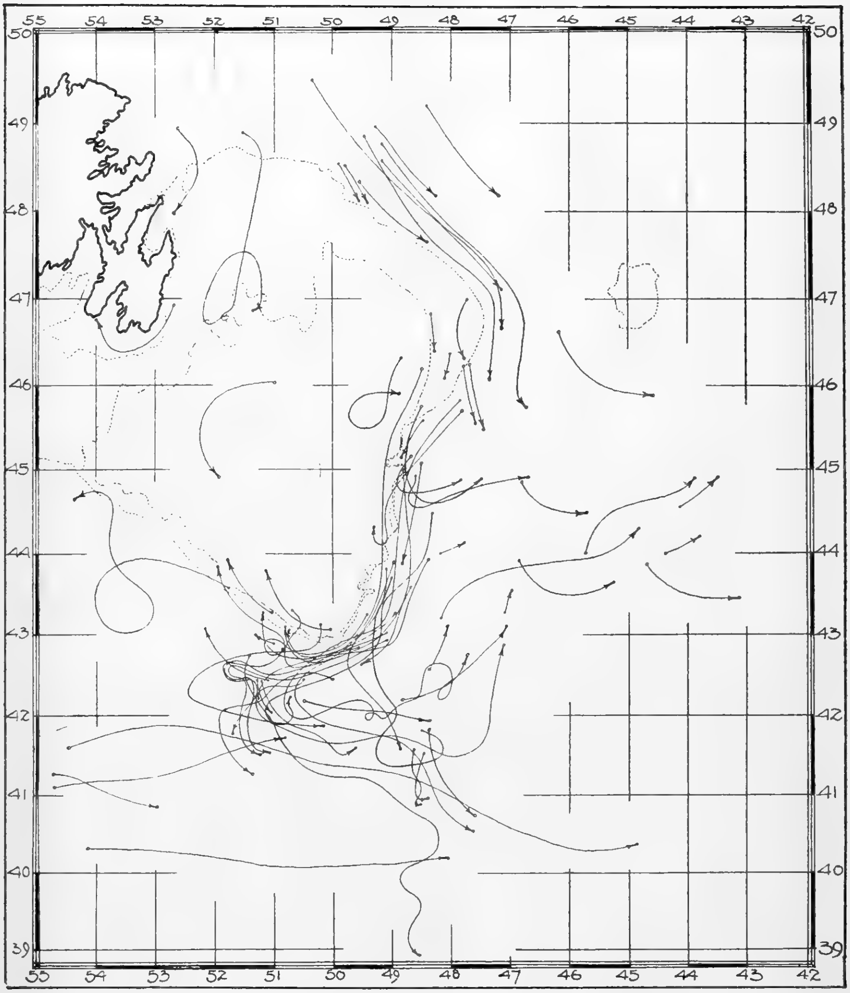

FIG. 22.—Chart of compiled drifts of icebergs, 1914-1926

SUMMARY OF ICEBERG RECORDS IN THE NORTH-WESTERN NORTH ATLANTIC, 1880-1926

In connection with the ice forecasting work described in the "Weather" section (pp. 31–48) it has been found necessary to collect the very best data from all sources on the amounts of ice from year to year and month to month. For the period 1880 to 1900 advantage was taken of the figures compiled by Mecking and also those of Schott, these investigators having based their comparative estimates of these years on records of the Deutsche Seewarte, the United States Hydrographic Office, the United States Weather Bureau, the United States Signal Service. We made an actual count of the number of icebergs south of Newfoundland by months for the period 1900–1926, and the records consulted in this task were those of the International Ice Patrol, and the United States Hydrographic Office. For the sake of record a table of the actual iceberg count is appended herewith, followed by a table of iceberg anomalies:

NUMBER OF ICEBERGS SOUTH OF NEWFOUNDLAND (48TH PARALLEL) IN WESTERN NORTH ATLANTIC

Year	Jan.	Feb.	Mar.	Apr.	May	June	July	Aug.	Sept.	Oct.	Nov.	Dec.	Annual
1900	10	0	0	5	32	33	6	1	1	1	0	0	89

[1] Based on March, 1903, with weight of 150 instead of 400.

The character of the iceberg seasons 1880–1926 is represented by the following table based on a value of 0 to 10:

Year	0	1	2	3	4	5	6	7	8	9
1880	4.7	2.4	6.1	4.7	6.4	7.4	4.0	5.0	4.3	3.5
1890	8.6	3.1	4.0	4.4	6.1	3.0	3.8	6.1	5.1	5.4
1900	3.0	3.0	2.5	7.3	4.1	7.4	4.7	6.4	3.8	8.6
1910	2.8	4.6	8.6	5.7	6.8	5.4	2.8	2.5	3.7	4.2
1920	5.1	6.8	5.9	4.1	2.0	3.3	4.3	-------	-------	-------

This table is represented graphically by Figure 23.

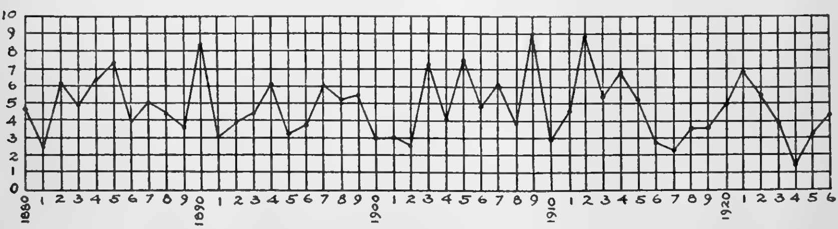

FIG. 23.—The iceberg character of the years 1880–1926, based on a scale 0 to 10. Mean value 4.8

We may now take the iceberg count for the period 1900–1926 and by computing the average of each series of months obtain the normal number of bergs for the western North Atlantic for each one of the 12 months.

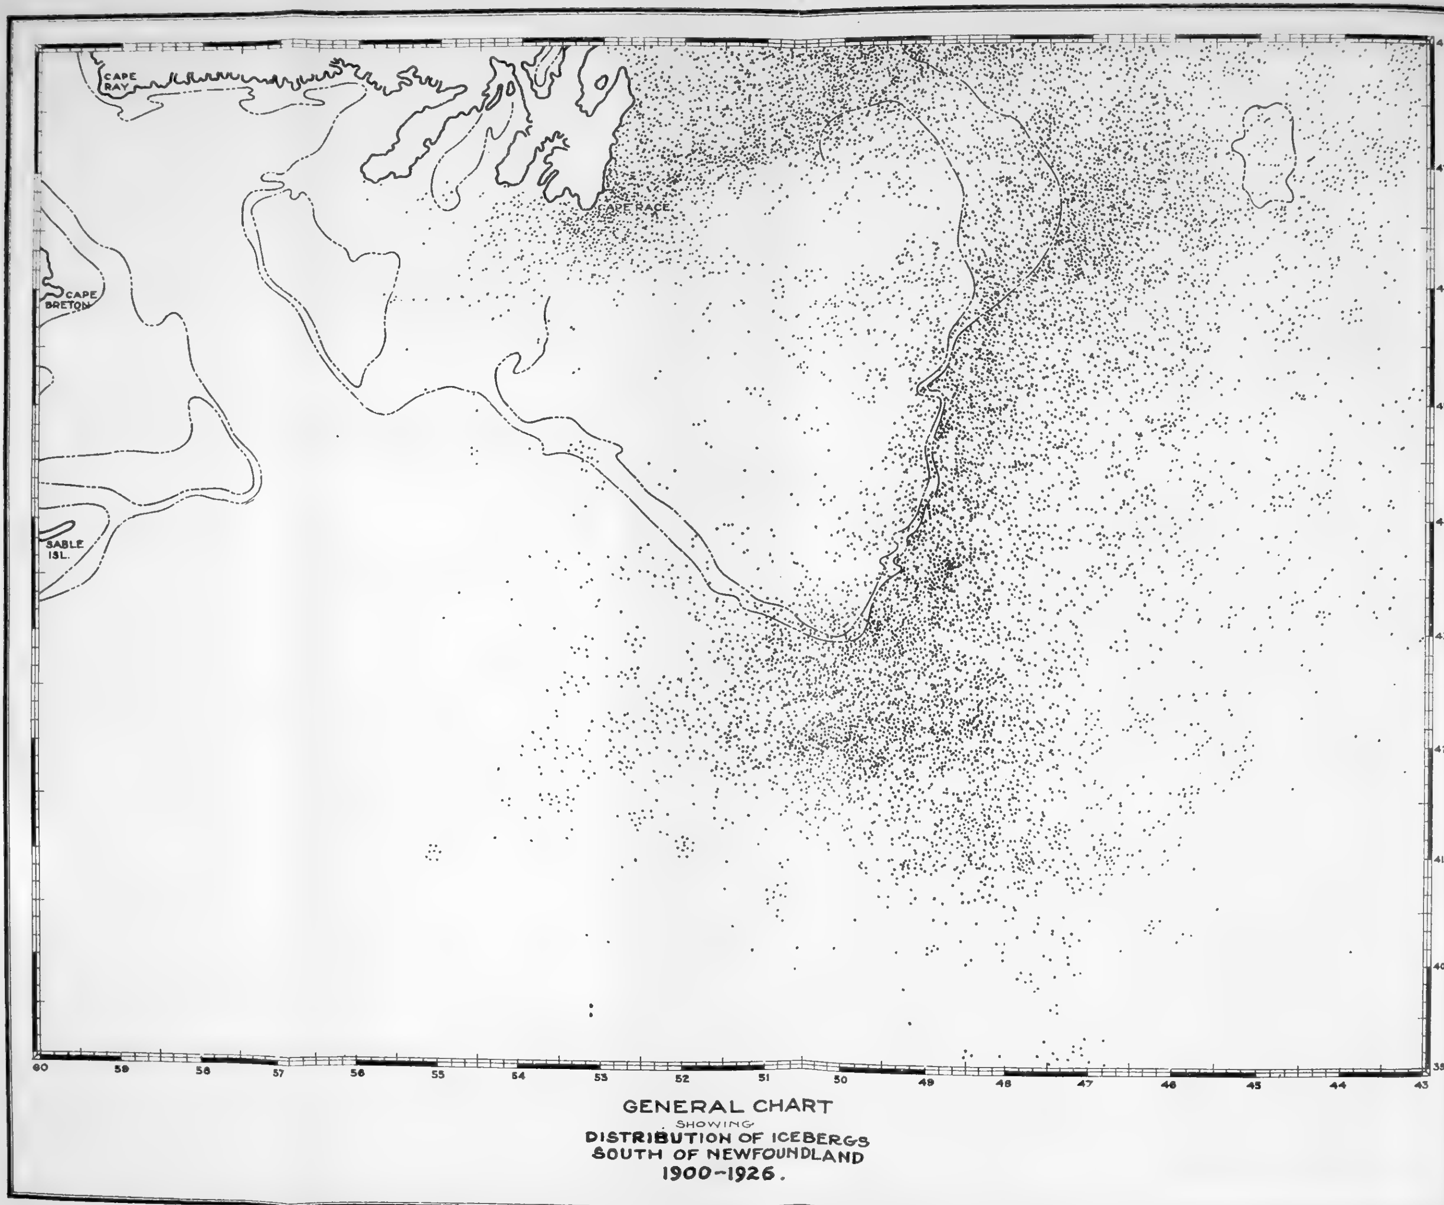

FIG. 25.—Distribution of icebergs south of Newfoundland, 1900–1926, compiled from steamer reports and ice-patrol reports contained in the weekly Hydrographic Bulletins of the United States Hydrographic Office

Normal number of icebergs south of the forty-eighth parallel (menace to the Cape Race tracks)

January	3	April	83	July	25	October	4
February	10	May	130	August	13	November	3
March	36	June	68	September	9	December	2

Normal number of icebergs south of the Grand Bank (menace to the United States to Europe tracks)

January	0	April	9	July	3	October	0
February	1	May	18	August	2	November	0
March	4	June	13	September	1	December	0

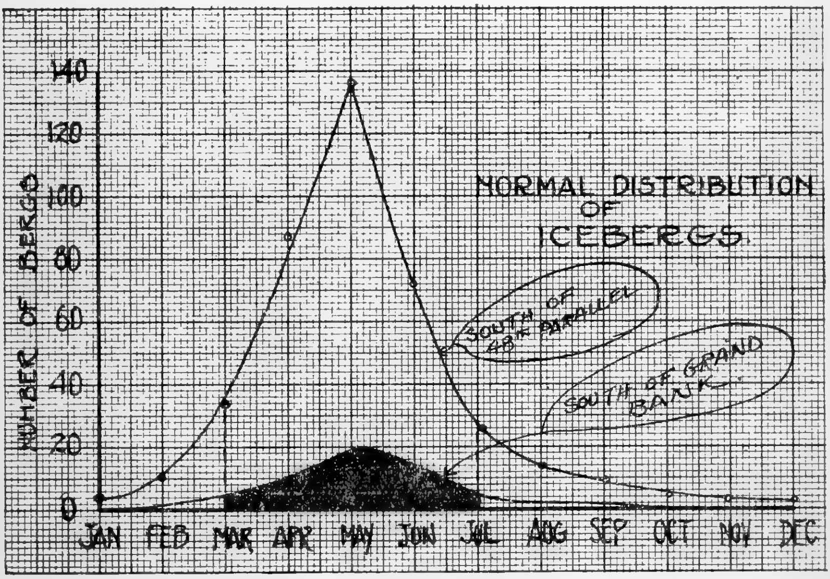

FIG. 24.—The normal monthly distribution of icebergs in the western North Atlantic—(*a*) south of Newfoundland (48th parallel); (*b*) South of the Grand Bank. The black area represents the span of the normal ice season as interpreted by the ice patrol

The monthly distribution throughout a normal year is represented by the two curves on Figure 24. The space between the two dotted vertical lines embraces the normal ice season, March to July. It can be seen from the foregoing that there are really no ice-free months on the Cape Race tracks, while there are only four such months on the United States to Europe tracks.

In the course of the research work which has been carried on by the International Ice Patrol there has been plotted on a chart the position of those icebergs reported by steamships during the period 1900–1926. This material has been taken from the file of United States Hydrographic Office publications, principally the Hydrographic Bulletin.

OCEANOGRAPHY

Oceanographic station data and dynamic calculations, 1926

δ_t at head of column 9 represents the value, density in situ.
V at head of column 10 represents the value, specific volume in situ.
$V-V_1$ at head of column 11 represents the value, anomaly of specific volume in situ.
E at head of column 12 represents the value, height in dynamic meters.
$E-E_1$ at head of column 13 represents the value, anomaly of dynamic height.

[b] Differs from observed, having been corrected for smooth curves of temperature, salinity, and density.

OCEANOGRAPHY

Edward H. Smith

It ought to be emphasized that the London convention which gave genesis to the idea of an ice patrol also laid particular stress upon the importance of collecting scientific data. It was believed that the patrol could give the most efficient economic service to shipping only when scientific methods were employed to support the practical work. Oceanographical investigations of the waters of the ice regions have, during the past 13 years of the service, gradually come to be recognized as contributing a clear and accurate insight into the behavior of floating ice. Such information is not only important for the patrol, but it likewise means greater safety for lives and ships on the North Atlantic. It is obvious that observations restricted solely to the surface do not furnish a true and complete picture of the circulation which is in process, and it is only by including the subsurface that we can hope to obtain a correct view of the interaction between the water masses as a whole.

The oceanographic information of which the patrol makes a complete analysis in arriving at conclusions regarding the behavior of ice, consists of the following:

(*a*) Vertical distribution of salinity, temperature, and density.

(*b*) Horizontal distribution of salinity, temperature, and density.

(*c*) Horizontal distribution of potential (current maps).

Ice scouting is the primary work of the patrol, and this means limiting the number of stations to the minimum and confining the observations to depths no greater than are essential for obtaining the true picture of the circulation. It is also necessary to remember that the more nearly simultaneous the observations can be, the more accurate picture is for the area covered. An ideal program, of course, includes a maximum number of stations distributed netlike over the area investigated and along lines running at right angles to the currents. Therefore, before commencing the observational work all available data as to the hydrographical nature of the ice regions should be carefully studied. This matter received the attention of the Interdepartmental Board on Ice Patrol as early as 1921, when a tentative program was formulated, which has been carried out more or less intensively ever since. The program was revised slightly in 1926 and is described here in some detail, because observations ought to be patterned along the same general lines for several years to come. A standardized program permits ready comparisons between a series of years.

GENERAL PROGRAM OF WORK

The oceanographic plan is based on five lines of stations which run more or less at right angles to the currents and to the general trend of the Grand Bank slopes along the following radials:

Line A: Length 60 miles, 3 stations.
Line B: Length 88 miles, 5 stations.
Line C: Length 100 miles, 5 stations.
Line D: Length 180 miles, 7 stations.
Line E: Length 60 miles, 4 stations.

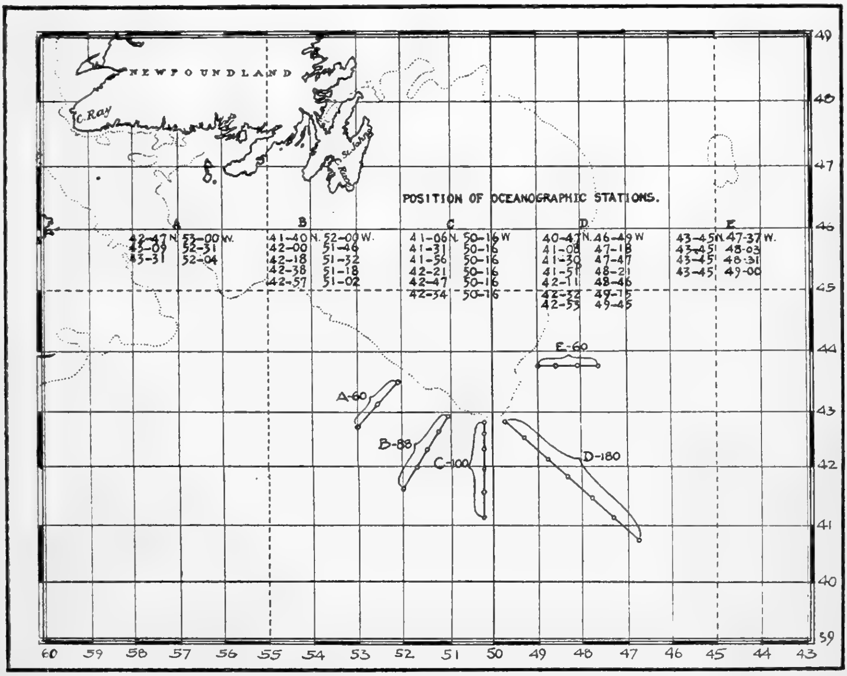

FIG. 26.—The selected position of stations upon which are based the oceanographic surveys conducted by the ice patrol

This distribution of stations permits a vertical examination of the water mass to be extended offshore from five different points along the slope of the Grand Bank, and it also allows us to determine the important physical variations taking place in the ice-infested waters. The distance between stations is set at 20 to 30 miles in order that all the principal features will be detected, and the stations are extended offshore from the Newfoundland shelf for a distance of 60 to 180 miles. The innermost stations are placed as far in on the continental slope as possible, and yet readings secured from the standard maximum depth of observation, 750 meters, without the weights touching bottom. It is important to take temperature and salinity

observations from a sufficient number of levels of depth in order that the change in physical character of the water may be followed in detail. It is equally important that observations be extended downward to abyssal regions where uniformity of conditions tend to prevail. The greatest changes per unit increase in depth in an ocean are generally in the surface layers, and the deeper we penetrate the more homogeneous becomes the mass. A characteristic graph of the density which is based on the two fundamentals, salinity and temperature, is shown in Figure 27. The upper 25 meters is generally kept more or less homogeneous by the mixing effect of the waves, a feature illustrated by the steepness of the density curve. The water column between 25 and 50 meters increases in density very rapidly, i. e., the water is very stable, and this is shown by the horizontality of the curve at A. We find a secondary unevenness in the curve between the 125 and 200 meters depth, B, which is often observed and attributed to the limit of depth of the seasonal effect. Below this point the curve gradually and constantly approaches a straight line as homogeneous abyssal water is entered. In accordance with this normal stratification, the ice patrol has adopted a minimum number of standard depths at which the observations for salinity and temperature are always taken, viz., 0, 25, 50, 125, 250, 450, and 750 meters. It has been found, however, that considerable circulation takes place even below 750 meters, if we proceed as far 120 miles offshore from the continental edge. Therefore it would seem desirable in future years to extend the observations at least to 1,200 meters.

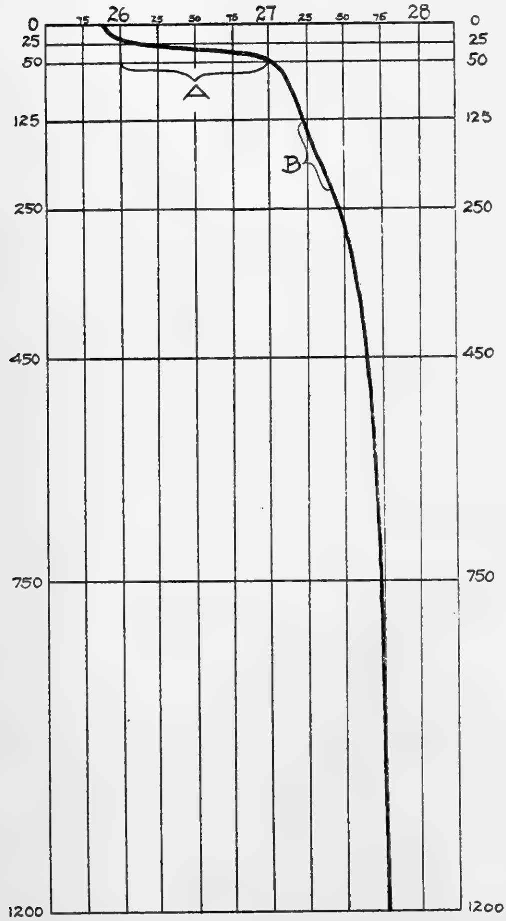

FIG. 27.—An example of the distribution of density with ocean depth

HOW TO AVOID ERRORS IN OBSERVATIONS

It is very easy for one not thoroughly schooled in the art of collecting observations of the temperature and salinity of a water column to make all sorts of errors. Usually the mistake is not detected until some later date when, alas, it is too late to repeat observations and rectify the error. It behooves observers to exercise the greatest care in order that the degree of accuracy be raised as high as possible, and the reputation of the records correspondingly enhanced. The following hints may be found useful by future investigators:

(1) The water bottles should be in the finest working condition, and should be gone over and oiled frequently.

(2) Guard carefully against a tendency for the bottle to close prematurely.

(3) Each bottle should be equipped with two thermometers.

(4) Thermometers should be functioning properly and kept under close observation.

(5) If thermometers in the same bottle do not check, they should be examined.

(6) The mercury column should be continuous from the bulb end when the bottles are lowered over the side.

(7) The meter wheel should be checked occasionally for accuracy of measurement.

(8) The wire should be guarded against kinks.

(9) The wire should be oiled occasionally.

(10) The wire should be vertical when the top messenger is released.

(11) Never take station observations if wire has a slant of more than 35° with the sea surface.

(12) Allow five minutes after lowering the instruments before releasing the first messenger.

(13) Determine time interval for bottom bottle to be tripped at various depths and do not start hoisting until this interval has expired.

(14) Do not capsize bottles when removing them from wire.

(15) Read thermometers with great care and note registration in record book.

(16) Each bottle should then be returned to its properly marked stall in the rack in order of sequence.

(17) When last bottle is being hoisted on board, or before, plot the temperature readings of the various depths of observation on cross-section paper. If the values do not form a smooth curve characteristic for the time and place, repeat suspicious observations immediately before leaving station. Ability to detect errors in temperature curves comes with experience.

(18) Citrate bottles should be clearly marked to indicate the station number and the particular depth from which filled.

(19) Stoppers on citrate bottles should be absolutely air-tight.

(20) Coach oceanographic party in teamwork.

(21) Determine salinity of water samples by running them through the electric salinity tester on board and in accordance with instructions for same.

(22) Test salinity values on cross section for smooth curve.

(23) Apply to stem temperature of deep-sea thermometers the proper correction for auxiliary thermometer reading.

(24) Obtain density values by entering temperature and salinity graph.

(25) Test densities for smooth curve on cross-section paper. (See fig. 27, p. 88.)

A PROBLEM THAT HANDICAPS THE ICE PATROL

One of the most important natural problems which has confronted the ice patrol has been the securing of advance information regarding the probable drift of ice after arrival at the gateway to the Atlantic (the vicinity of the Tail of the Grand Bank). If we glance at a general map of the northwestern North Atlantic we may trace the general course followed both by the current and by the ice stream southwards along the continental slope from Baffin Land to the Tail of the Grand Bank without great change in direction for a distance of 1,800 miles. But when the cold Arctic water is discharged past the Tail of the Bank it is no longer preserved by the general trend of the continental slope, but is forced to meet directly the easterly moving masses of, or associated with, the Gulf Stream. It is at this point that the course of the current, and likewise its freight of ice, is subjected to great variations in direction. Naturally it is extremely desirable for the patrol to be able to disseminate to shipping, whether the ice will be deflected northward again into the shallow shelf waters, or whether it will be swept southward across the North Atlantic Lane Routes, and so create a very grave menace to shipping. If the patrol had knowledge of the drift tracks which bergs would follow after arrival at the gateway to the Atlantic, much more detailed information could be furnished to approaching vessels, especially during the protracted periods when fog enshrouds this cold-water region.

NEW METHODS IN OCEANOGRAPHY INTRODUCED ON ICE PATROL

The interdepartmental board charged with the administration of ice patrol had for some time been following the modern methods pursued in oceanography, particularly those taught at the Geophysical Institute, Bergen, Norway. The board believed that these methods had a practical application to the ice patrol's unique problem, as described in the preceding paragraph. The new thought in this branch of oceanography was more or less widely introduced by Prof. V. Bjerknes and others [1] in a treatise on the dynamics. Since that time several Scandinavian oceanographers have attained such success in further applying Bjerknes' basic formula to oceanographic investigations that arrangements were made for me to attend the Geophysical Institute, Bergen, 1924–25, for a year's study with Prof. Helland-Hansen on the theory of free motion and for instruction in the various methods of illustration. The oceanographic records of the ice patrol, some 3,000 observations of temperature and salinity from various depths and places in the ice regions, were also treated at the Geophysical Institute by mathematical computation. It is hoped to have this research published. The first maps thus ever

---

[1] Dynamic Meteorology and Hydrography. Carnegie Inst. Pub., Washington, 1910–11.

drawn of the circulation in the ice regions indicate a close agreement between the calculated currents (velocity and direction) and the actual drifts of bergs at the time and place. Dynamic oceanography provides an easy and efficient means for mapping currents over extensive ocean surfaces, which guarantees it wide employment in future hydrographical surveys. If properly employed on ice patrol, moreover, it promises some day to vindicate the belief of the members of the London Convention which established the ice patrol, viz.:

> Skilled navigators and scientists are confident, partly as a result of Arctic and Anarctic explorations of recent years, that a thorough study and observation of ice conditions and formation, and of the Labrador current and other currents, the natural laws governing the formation and the movements of ice in the North Atlantic may be determined, at least to the extent of permitting approximate forecasts, similar to recent meteorological forecasts, which will contribute to safer ocean navigation.

If we steam the patrol vessel over the critical ice area, taking observations of the salinity and temperature at selected places, the data thus collected furnish the material for calculating the direction and velocity of the currents.[2]

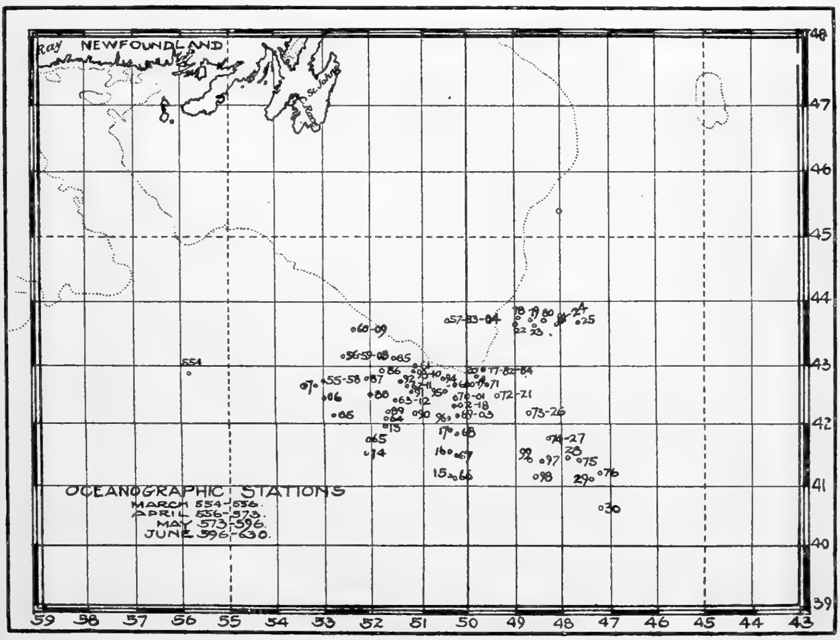

FIG. 28.—Chart of oceanographic stations occupied in 1926

STATION WORK PERFORMED IN 1926

The 1926 ice season marked the first attempts to employ the scientific methods explained in United States Treasury Bulletin No. 14,

[2] Smith, Edward H.: A Practical Method for Determining Ocean Currents. U. S. Treas. Dept. Bull. No. 14, 1925.

and the work was bent wholly towards contributing direct practical information on the behavior of those icebergs that drifted south of the Tail of the Grand Bank. In the course of the season a total of 76 stations were taken, all but three of which were occupied in the deep water off the slope to a depth of 750 meters. This number of stations is less than for 1923 or for 1924; but their value was consequently greatly enhanced by their being well distributed over the area to be surveyed, with each station in the set taken in rapid succession. We were handicapped during the early part of the season by the breaking down of the oceanographic winches on board both the *Tampa* and the *Modoc*, so that the first set of stations was not actually begun until April 29, after the patrol had been in progress more than a month. It was deemed best to make a general survey of the entire ice area at the beginning of the season and a second one at its close. During the progress of the season it was not found possible to make more than one survey and this was confined to a comparatively small but important area off the southwest slope of the Bank. The critical ice area is of such great extent that it requires at least a total of 12 to 14 stations to delineate the courses of the currents with any accuracy. A satisfactory survey of the entire region around the Tail was afforded by Sets I and III with a total of 26 stations.

SOME FEATURES REVEALED BY THE VERTICAL SECTIONS

The vertical sections show the distribution of temperature, salinity, and specific volume for the following groups of stations:

Section I: West-southwest slope, stations 558–560, figures 29 and 30.

Section II: Southwest slope, stations 557–565, figures 31 and 32.

Section III: South slope, stations 566–570, figures 33 and 34.

Section IV: Southeast slope, stations 571–576, figures 35 and 36.

Section V: East slope, stations 578–581, figures 37 and 38.

Section VI: West-southwest, station 607–609, figures 39 and 40.

Section VII: Southwest slope, station 610–614, figures 41 and 42.

Section VIII: South slope, station 615–619, figures 43 and 44.

Section IX: Southeast slope, station 620–630, figures 45 and 46.

Section X: East slope, station 622–625, figures 47 and 48.

Since vertical sections normal to the Grand Bank slopes have been taken and discussed repeatedly in former ice seasons, only brief comment on the principal features is called for.

Section I: The striking thing about this profile, Figure 29, is the shelf of icy water (temperature below 0° C.), that hugged the slope between 100 and 200 meters, and extended out about 20 miles from the edge. The density wall, as illustrated in Figure 30, was well developed at the time with its highest point approximately 45 miles seaward from the slope.

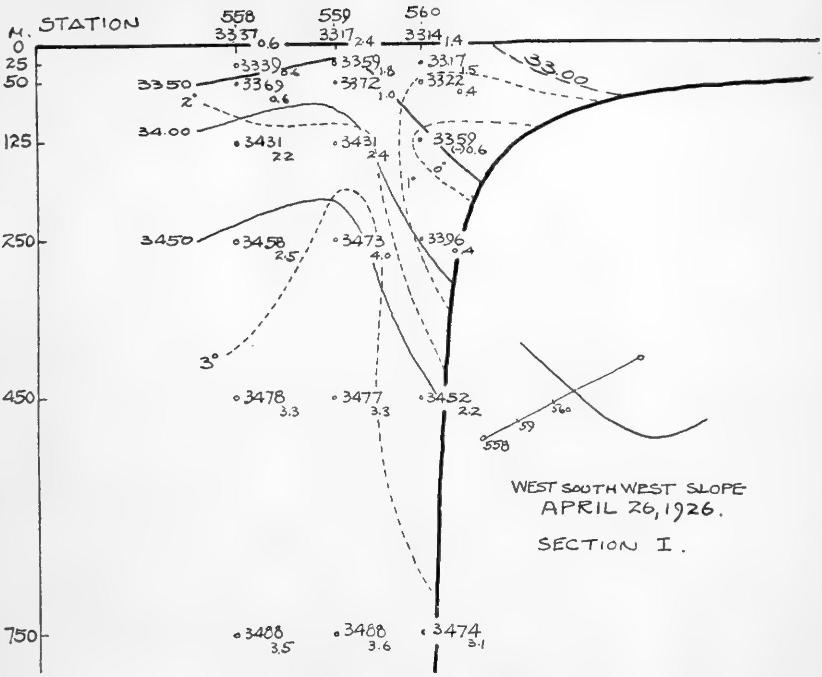

FIG. 29.—Distribution of temperature and salinity

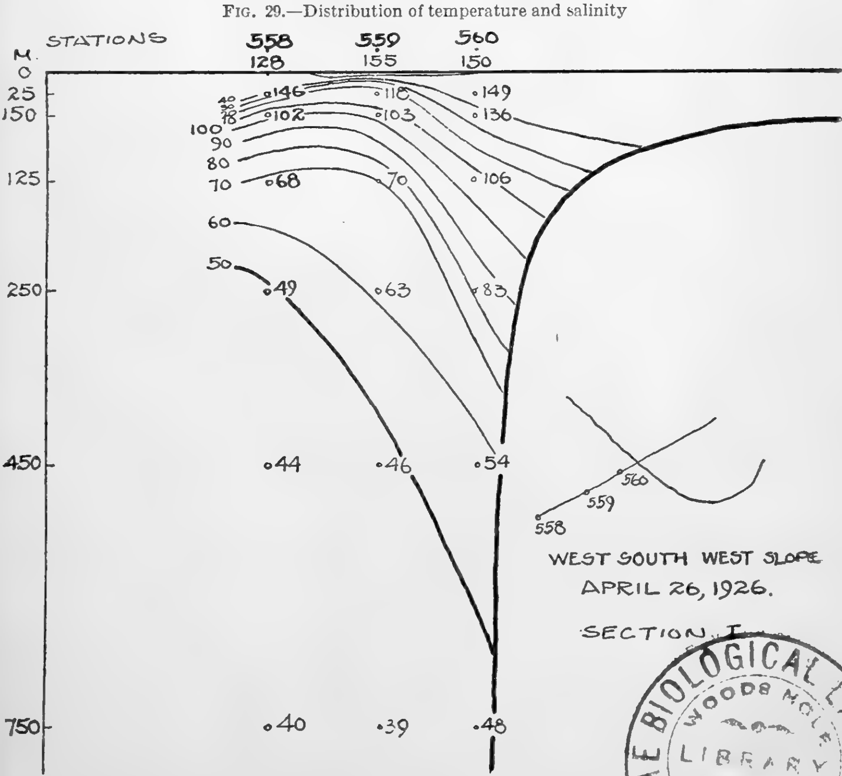

FIG. 30.—Distribution of specific volume

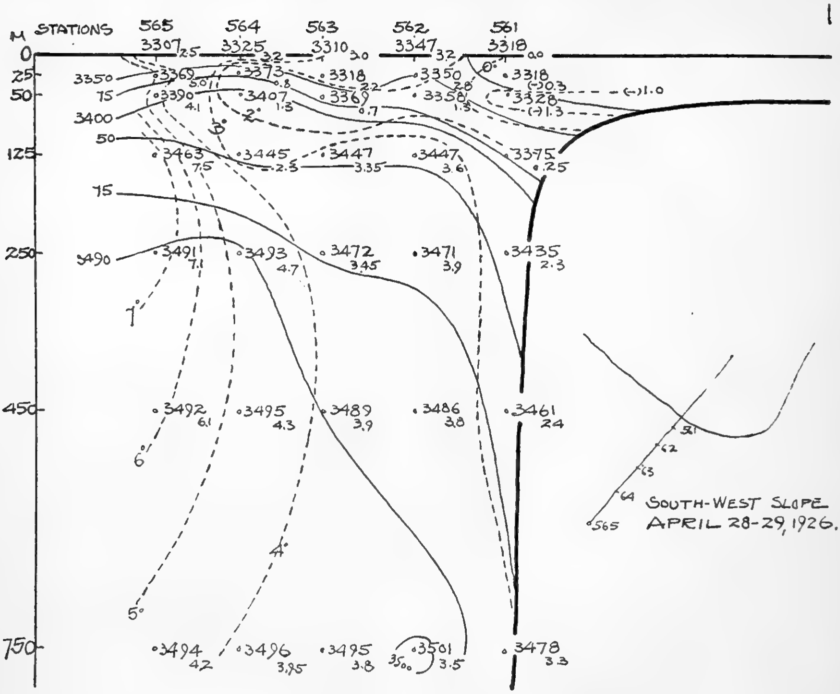

FIG. 31.—Distribution of temperature and salinity

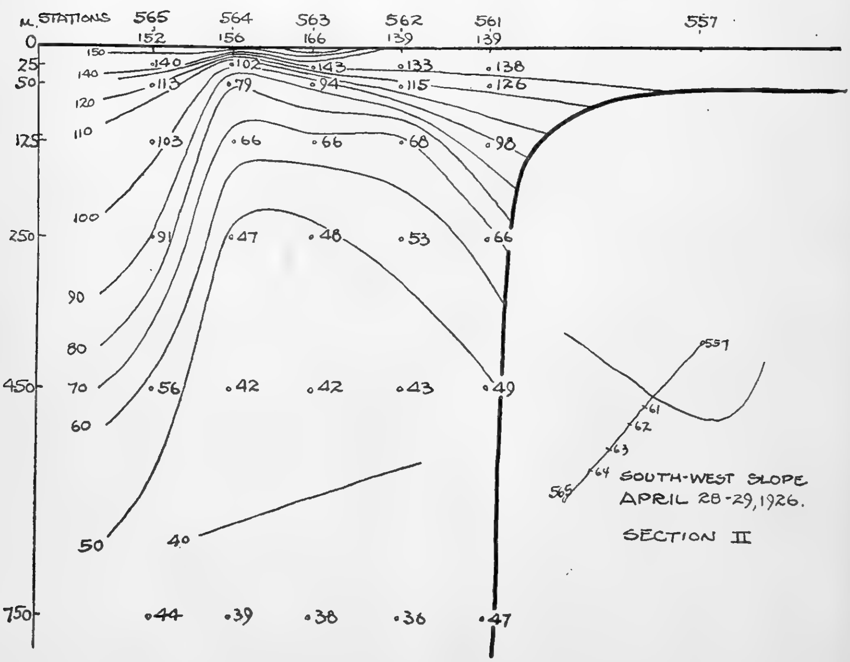

FIG. 32.—Distribution of specific volume

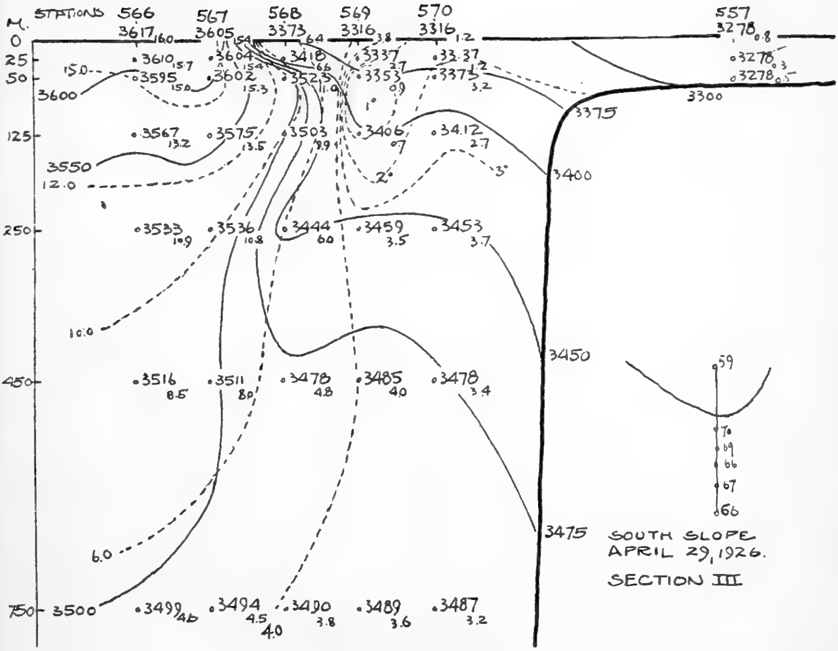

FIG. 33.—Distribution of temperature and salinity

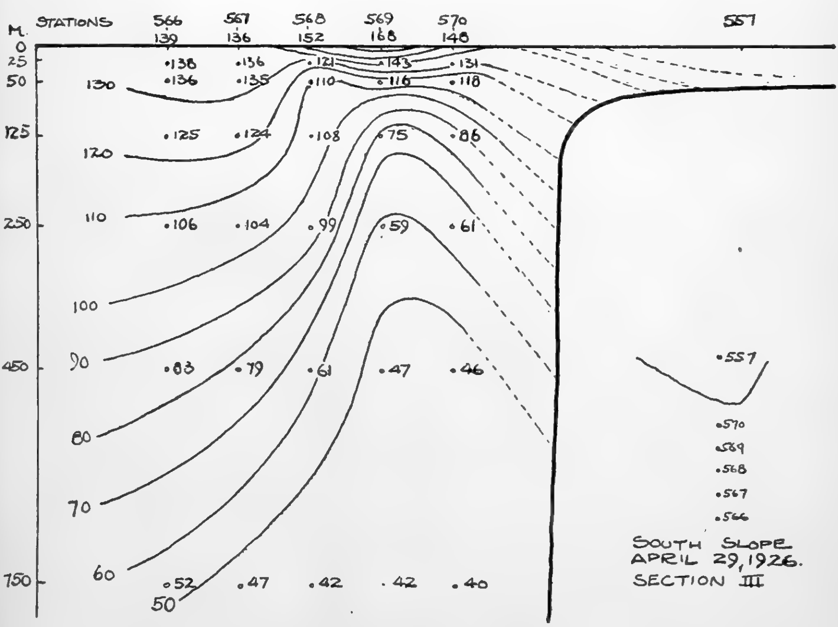

FIG. 34.—Distribution of specific volume

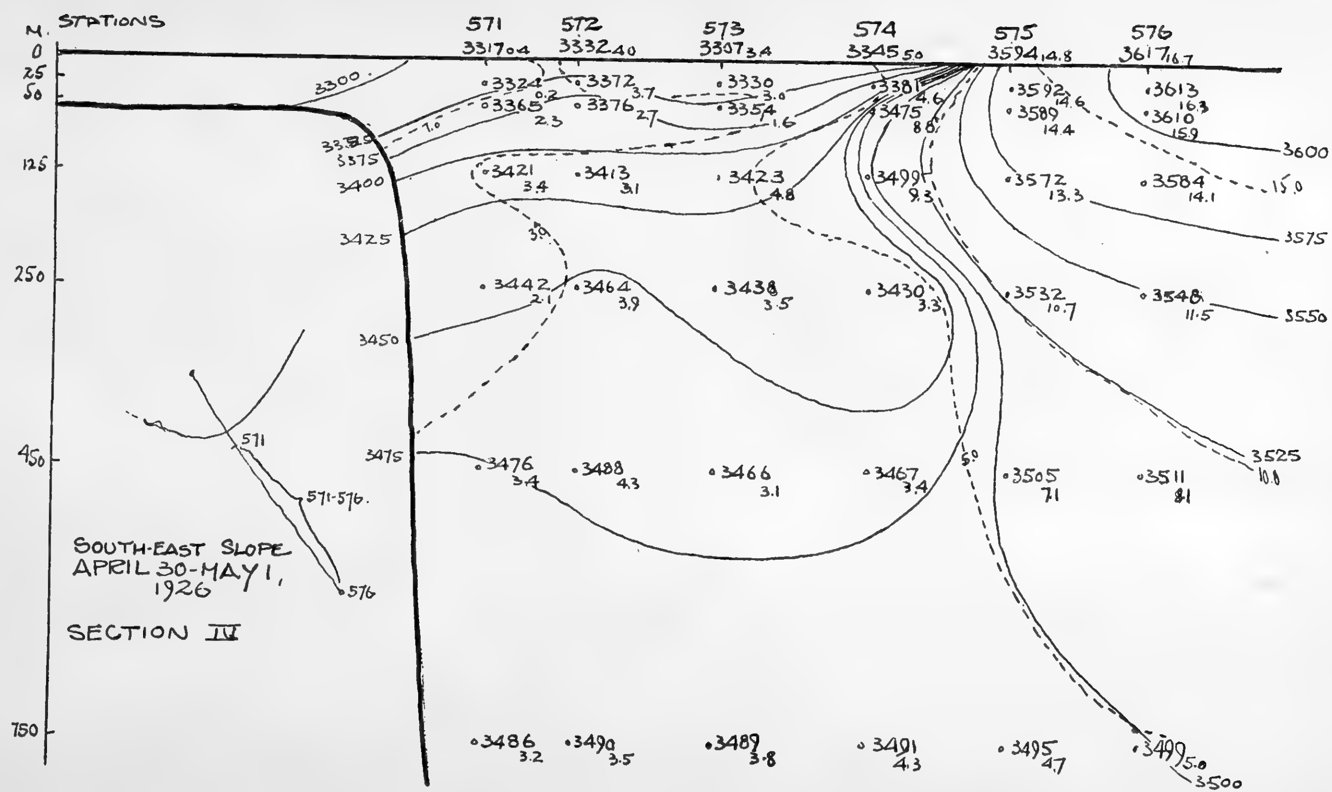

FIG. 35.—Distribution of temperature and salinity

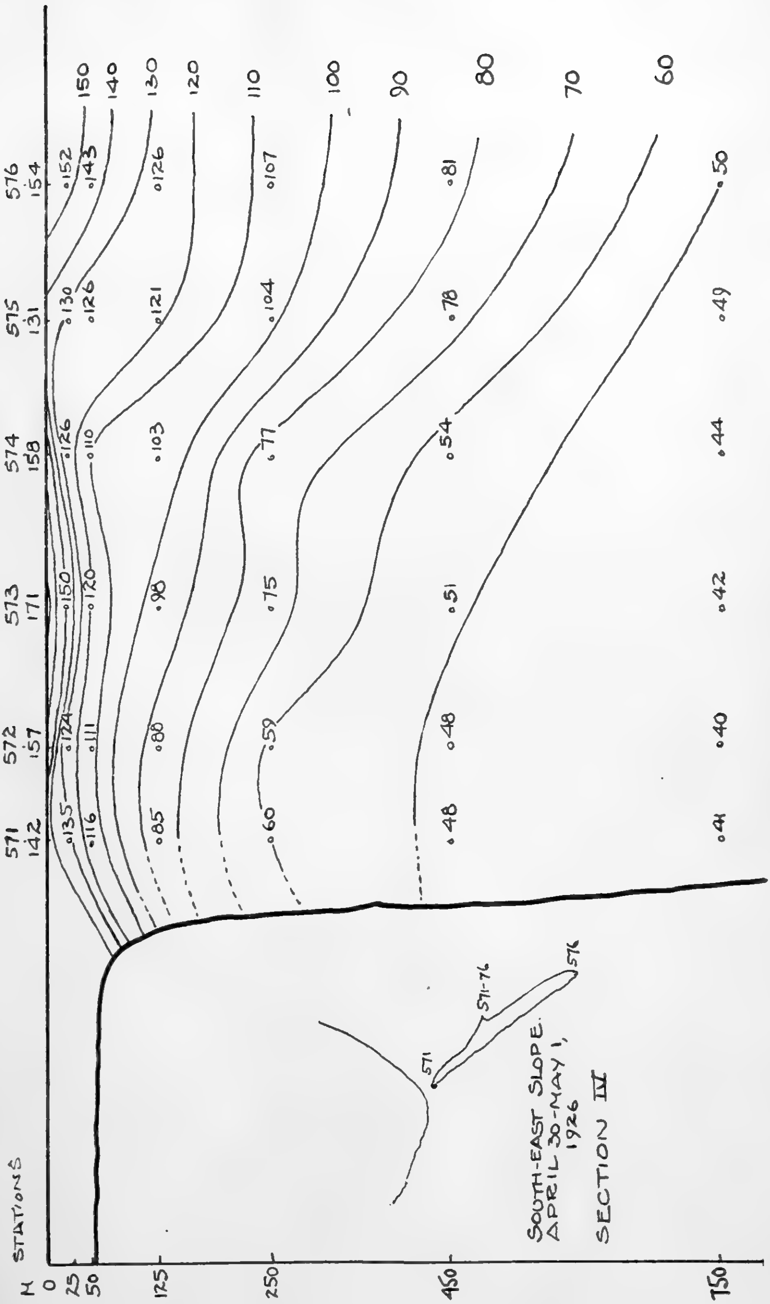

FIG. 36.—Distribution of specific volume

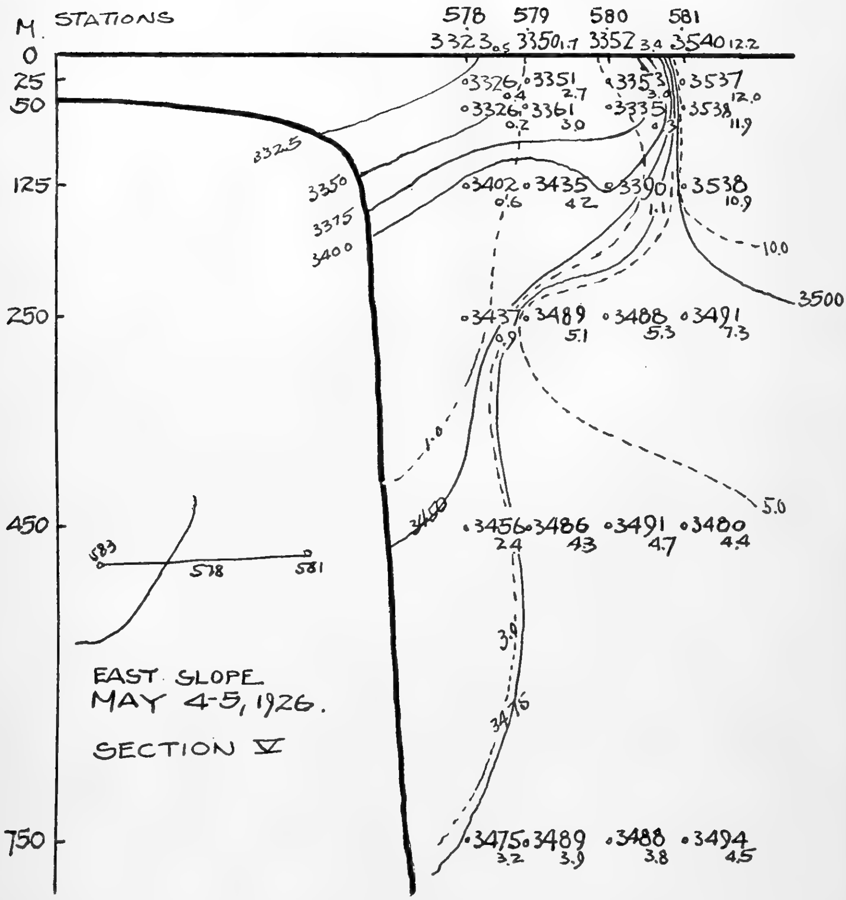

FIG. 37.—Distribution of temperature and salinity

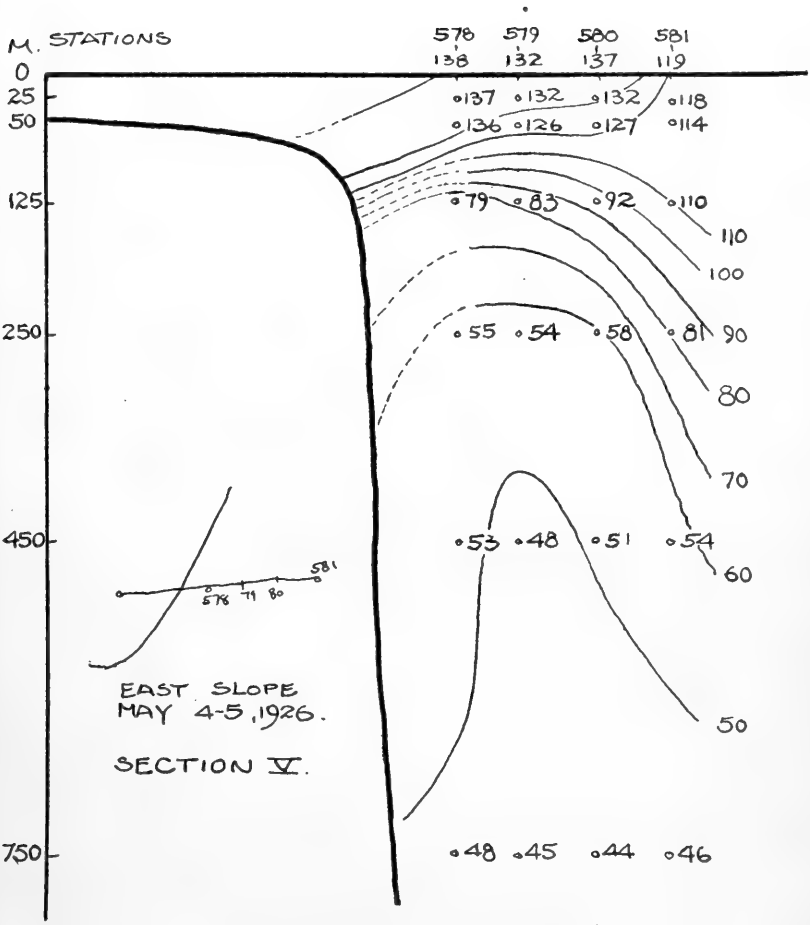

FIG. 38.—Distribution of specific volume

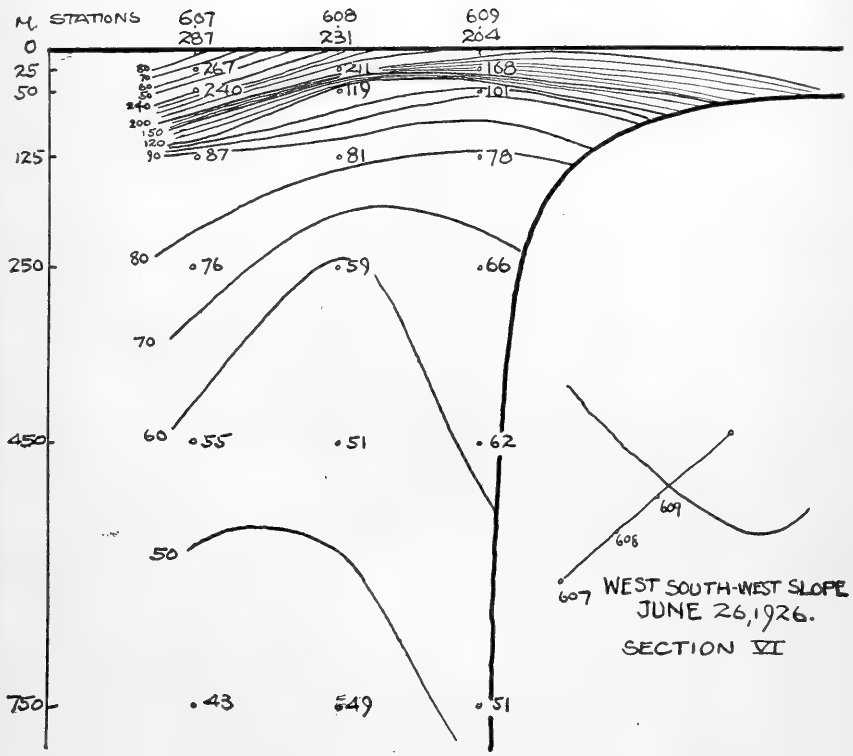

FIG. 40.—Distribution of specific volume

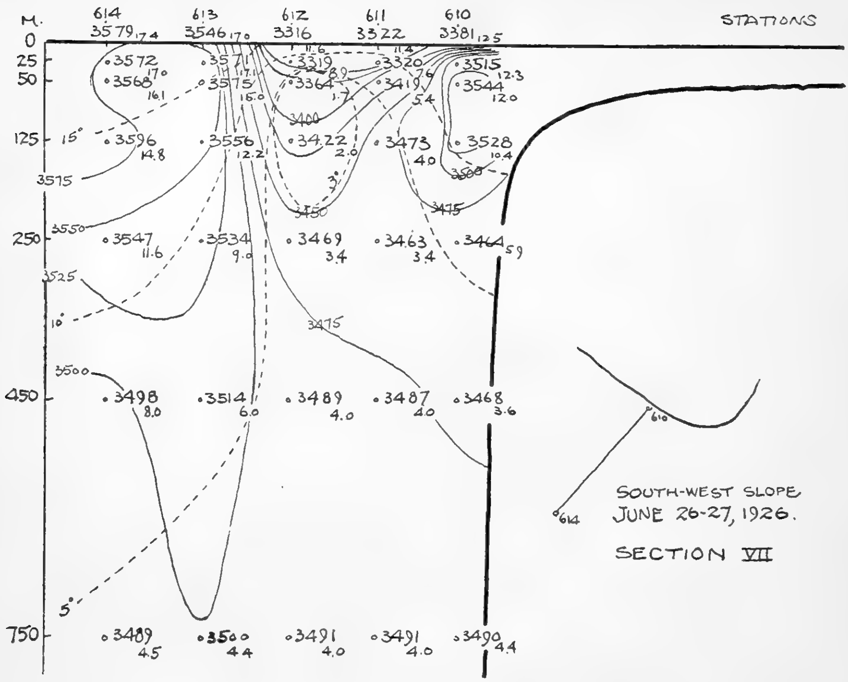

FIG. 41.—Distribution of temperature and salinity

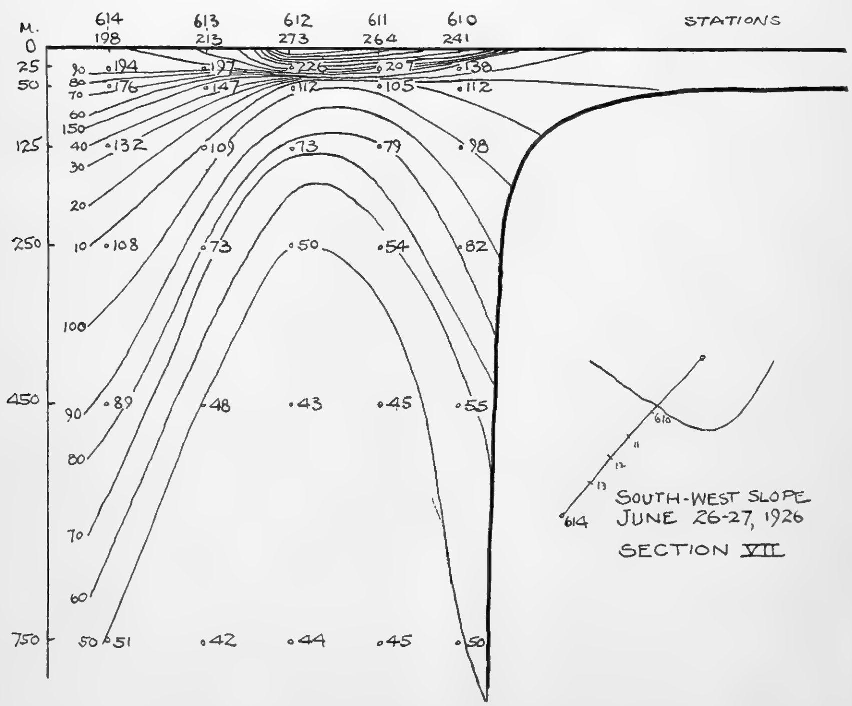

FIG. 42.—Distribution of specific volume

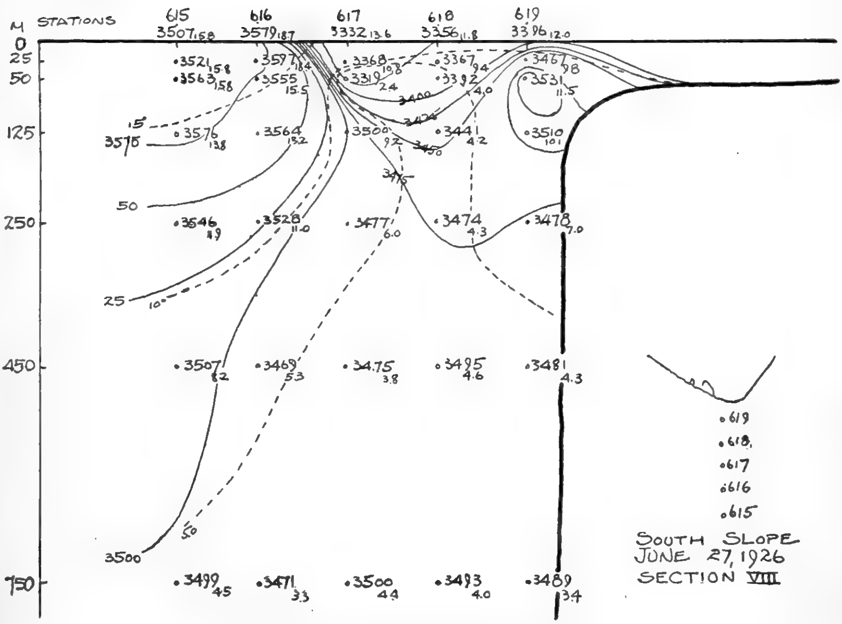

FIG. 43.—Distribution of temperature and salinity

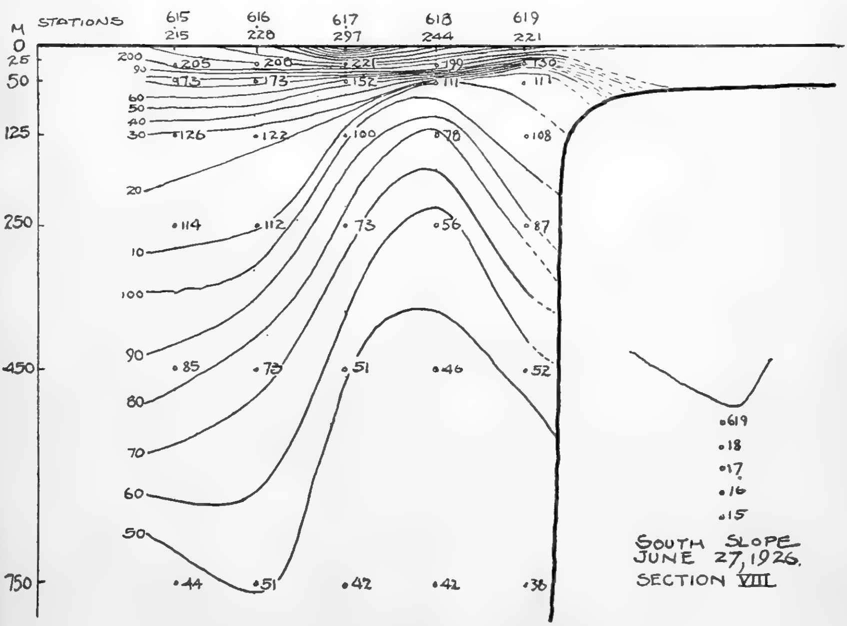

FIG. 44.—Distribution of specific volume

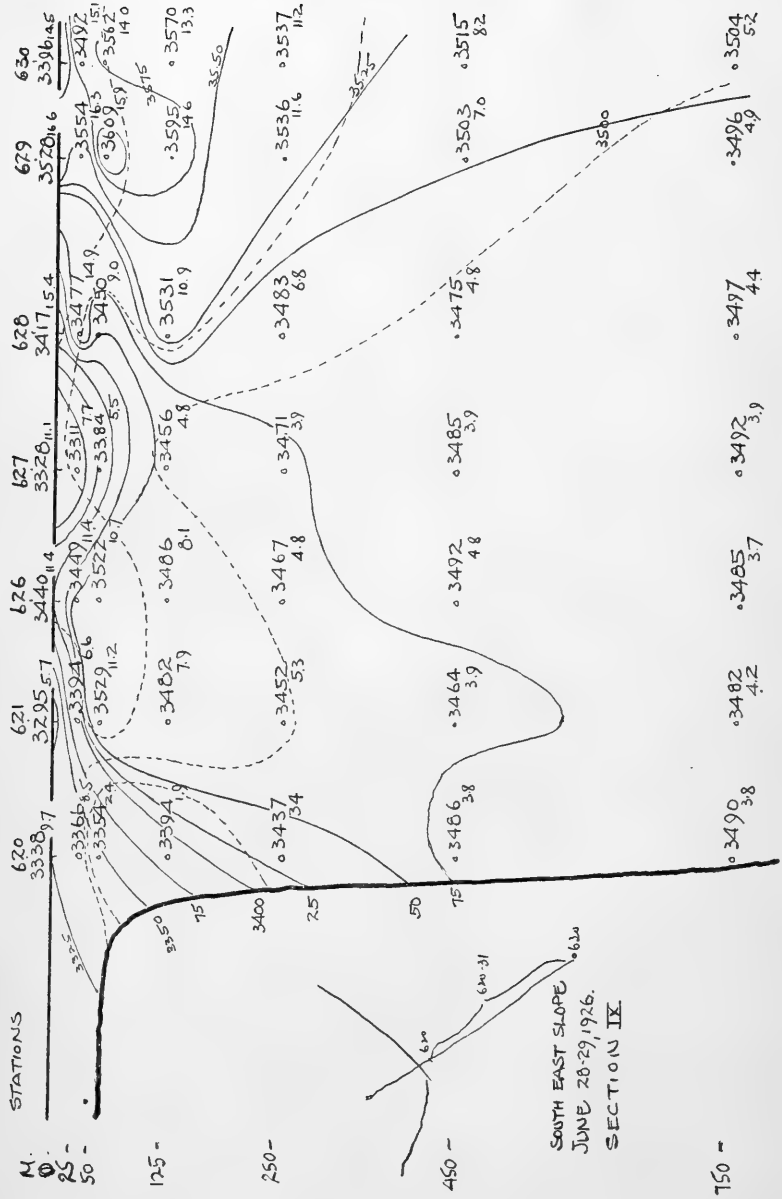

FIG. 45.—Distribution of temperature and salinity

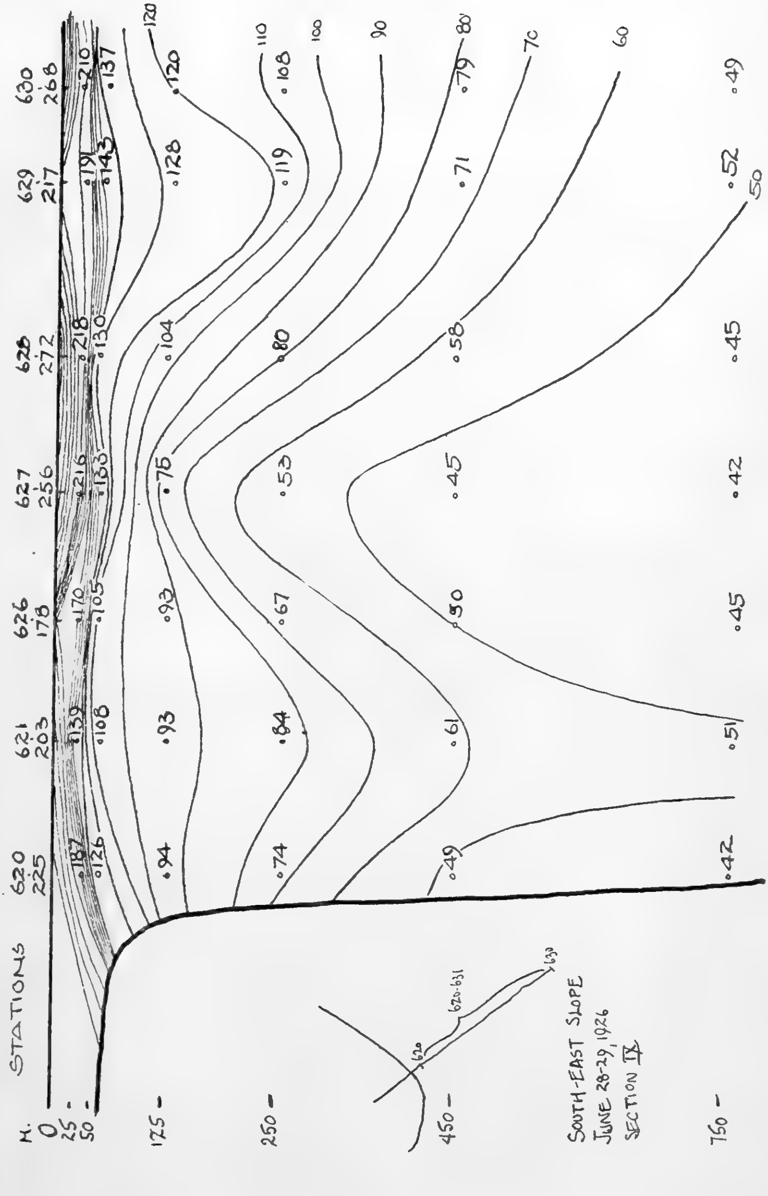

FIG. 46.—Distribution of specific volume

Section II: A cold surface layer 125 meters in thickness spread out from the edge for a distance of 75 miles. The corresponding profile anomaly of specific volume, Figure 32, indicates a much steeper slope to the isosteres on the offshore side of the density wall than on the inshore.

Section III: No water colder than 0° C. was found at the Tail on April 29, despite the fact that water colder than zero was then

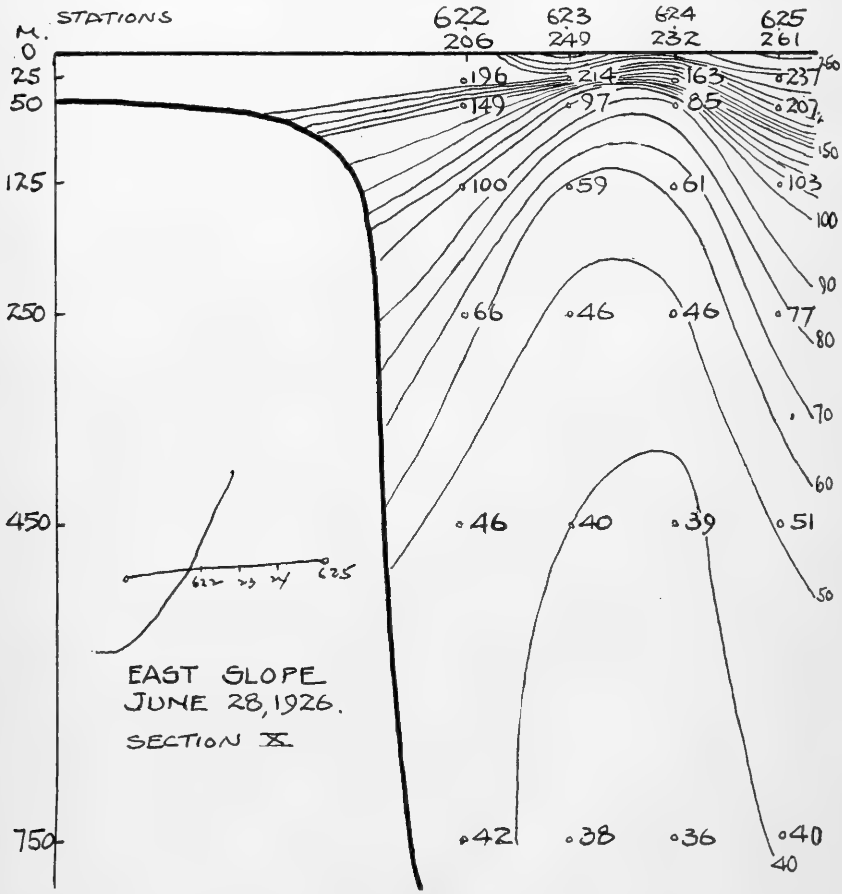

FIG. 47.—Distribution of temperature and salinity

bathing the slope farther to the northwest. The coldest water at the Tail, 1°, then took the form of a closed core at a depth of 50 to 100 meters, situated about 45 miles off the slope. The warm salty water at the outer end of this section is unmistakably that of the Gulf Stream. The density wall, as shown by Figure 34, page 95, was then well developed located near station 569, 45 miles offshore from the Tail. A comparison of Figures 33 and 34, page 95, indicates that the density wall

was then approximately 25 miles inshore of the "cold" temperature wall.

Section IV: No extremely cold water was found in this section, but the offshore stations 575 and 576 showed the effects of warm tropical water. The isosteres have a gentle, irregular slope from the inshore station, 571, out to the very end of the picture.

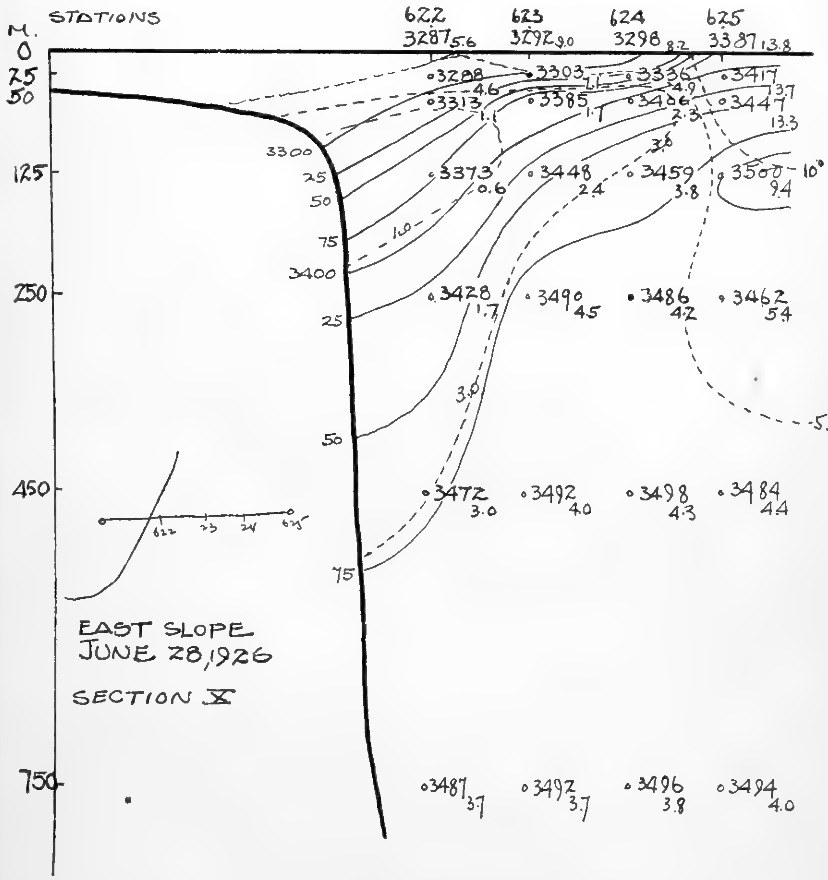

FIG. 48.—Distribution of specific volume

Section V: The inner edge of the Gulf Stream was reached at station 581 while the inshore stations showed no water colder than 0° C. The density wall lay 25 miles inside of the "cold" temperature wall. (Cf. fig. 37 with fig. 38, pp. 98, 99.)

Section VI: To our surprise a pool of relatively warm and fresh water was found at the offshore station on this section. It is difficult, to explain its source unless it had drifted out from the Grand Bank, curling around the end of the cold current which usually extends northwestward along the slope from the Tail, at that season. Doubt-

less the body of warm salty water which bathed the slope inshore on this section had its source in the inner edge of the Gulf Stream, the development of this invasion is plainly discernible on the horizontal charts of circulation. The increased number of isosteres in the profile of specific volume (fig. 40), over what were present in this locality six weeks earlier (fig. 30) represents the influence of increased solar warming of the surface layers.

Section VII: A connection with the warm salty water observed in Figure 39, is to be observed in this section (fig. 41) at the slope stations. The high temperatures and salinities at the two outer stations plainly indicate that the northern edge of the Gulf Stream then lay approximately 75 miles off the southwest slope. The density wall (fig. 42) was 20 to 25 miles inshore of the cold wall.

Section VIII: Again in this section we see a trace of tropical water along the southwest slope wedged in against the bank. The density wall at the Tail was about 30 miles inside of the temperature wall.

Sections IX and X exhibit no unusual characteristics from those observed in earlier sections at the same places.

DISCUSSION OF THE CIRCULATION IN THE HORIZONTAL PLANE

The total of 76 stations have, for the purposes of horizontal illustration, been divided into three groups which are separated from one another by a space of at least two weeks in time. They have been arranged as follows:

Set I: April 29 to May 5, a total of 25 stations embodied in Figures 49, 50, 51, 52.

Set. II: May 18 to 20, a total of 13 stations embodied in Figures 53, 54, 55, 56.

Set III: June 25 to 29, a total of 27 stations embodied in Figures 57, 58, 59, 60.

SET I

The 175 density values obtained from 25 stations, 558 to 583, taken April 29 to May 5, were subjected to mathematical computations described in United States Treasury Department Bulletin No. 14, giving the values shown in the last four columns in the oceanographic station table, page 78. Since we assumed that the maximum depth of observation, 750 meters (or decibars), was a level isobaric plane, the dynamic values of 728 + given on the charts (figs. 49, 53, and 57) represent the height of the sea surface in dynamic meters at each station. (See Oceanographic station table, p. 78, for a detailed record of these data.) The dynamic heights have been plotted at the proper station positions on Figure 49, page 109, and contour lines delineating the topography of the sea surface were drawn in similar fashion to those which appear on an ordinary

isobaric weather map. The dynamic topographical map (fig. 49) is read also in the same manner as one reads a meteorological map. The oceanic situation around the Tail of the Grand Bank April 29 to May 5 may be described as follows: A "low" or hollow in the sea surface lay centered off the southwest slope of the Grand Bank with a trough, circumscribed by the contour of 728.70 dynamic meters, extended around the Tail to the northeastward more or less paralleling the 100-fathom curve. The sea surface was relatively high in over the Bank itself and at the outermost stations offshore. A hill of water, figuratively, lay centered about 65 miles southeastward of the Tail.

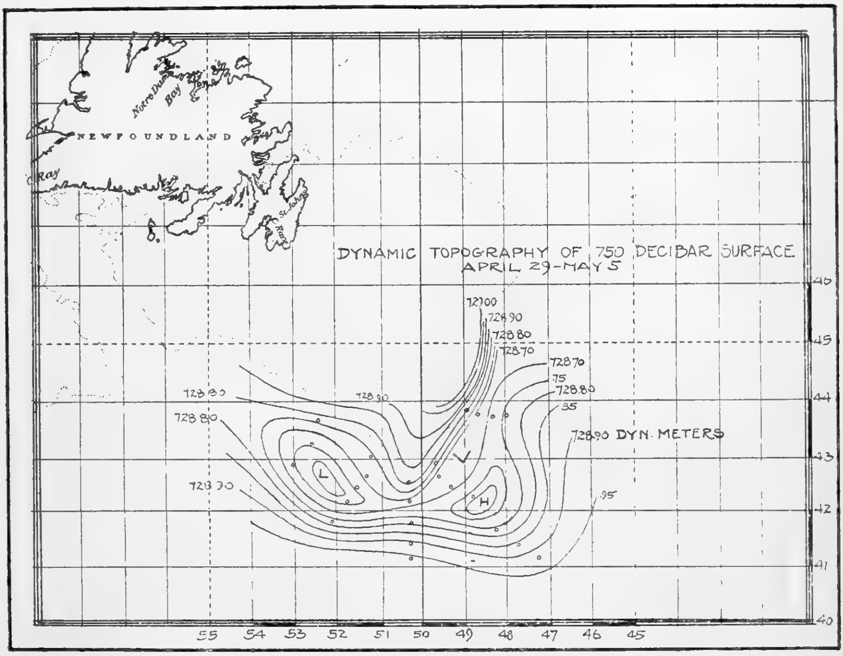

FIG. 49.—Set I. Dynamic topographical map

The circulation of the water, which will follow this dynamic topography of the surfaces is in general as on a weather map, anticlockwise around the "lows" and clockwise around the "highs." Figure 50, page 110, indicates the direction of flow of the water by means of the arrows, and the numerals represent in knots per hour the velocity of the current at the particular place and time. The velocities were calculated upon the assumption that the water had no motion at a depth of 750 decibars (meters). Such, however, was not literally the case, especially offshore in the Gulf Stream, but inasmuch as 750 decibars was the limit of depth to which our observations extended, it is taken arbitrarily as the depth at which motion most nearly approached zero. Reference to Figure 50, page 110, shows

FIG. 50.—Set I. Direction and velocity of the currents

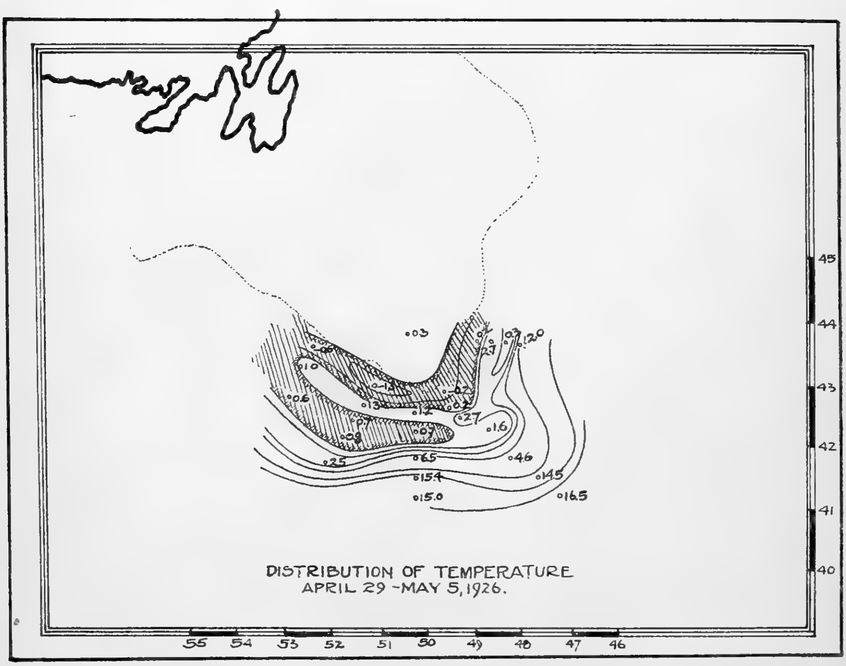

FIG. 51.—Set I. Distribution of cold and warm water

that the cold current was running swiftest along the east side of the Bank at the rate of 1.4 knots per hour, but it decreased to 0.7 knot 60 miles farther south at the Tail. The inshore set (Labrador current) curled around the Tail and flowed northwestward parallel with the continental edge, a distance of 150 miles, as far as our observations extended in that direction. Reaching that locality, a great portion of the current eddied offshore and back to the eastward, forming a vast anticyclonic vortex off the southwest slope. The most rapid rate of flow was 1 knot, located southwest of the Bank, as shown on Figure 50, page 110. The easterly moving water masses were split by a clockwise eddy when they reached a point

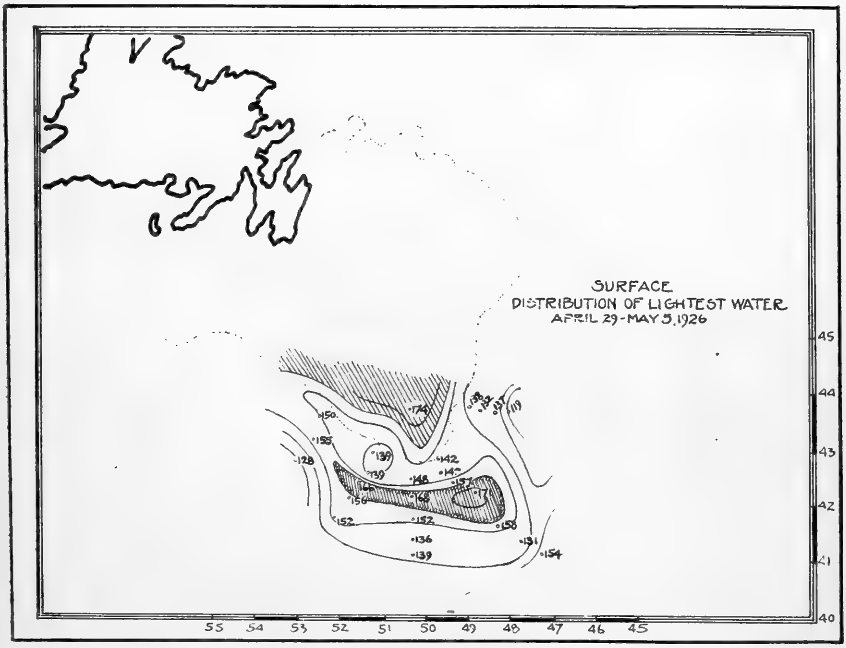

FIG. 52.—Set I. Distribution of light and heavy water on the surface of the sea

southeast of the Tail, but just to the northeast of this point the branches rejoined. The northeasterly counterset was only 25 miles off the eastern edge of the Bank in latitude 44°, but it was weak—0.2 of a knot per hour.

The distribution of cold water, as shown by Figure 51, page 110, is good evidence which supports the general scheme of circulation calculated and portrayed on Figure 50, page 110. The cold water from the north was transported to the Tail and thence along the southwest slope of the Grand Bank as far as our observations in that direction extended. The shape and position of the shaded area of water less than 1° C. (fig. 51, p. 110), clearly indicates that this cold water after being brought to the region of the southwest slope was

carried back to the eastward in the form of a counterset, separated from the westerly moving stream inshore by a strip of water about 10 miles in width and with a temperature higher than 1°. The fourth sketch of this set of observations, April 29 to May 5 (fig. 52, p. 111), illustrates the distribution on the surface around the Tail of the lightest water.

The lightest water, which has been inclosed in a shaded area, extended parallel with the slope some 35 miles to the seaward of the 100-fathom contour and had heavier water on either side. Light water also was found in over the Bank itself.

SET II

A hollow in the sea surface, the center of which was 10 dynamic centimeters lower than at any other point around the Tail, is to be

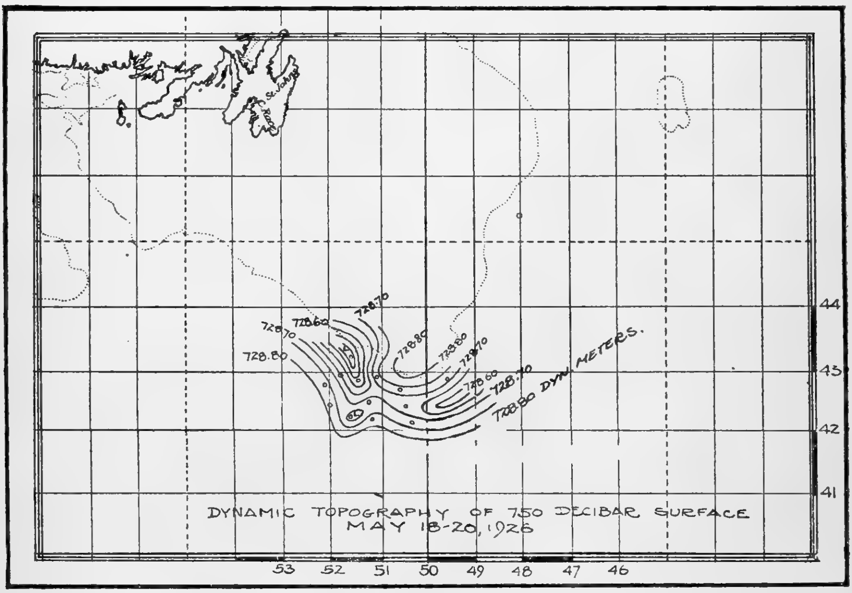

FIG. 53.—Set II. Dynamic topographical map

noted on Figure 53. The same trough of 728.70 dynamic meters that was recorded around the Tail of the Bank two weeks earlier is seen here stretched along the slope. The sea surface was relatively high in over the Bank and offshore at the outer stations, all of which conditions agree with those previously observed this season.

The oceanic situation for May 18 to 20 (fig. 53) reveals the fact that an important change had taken place since the first week in May (fig. 49). These two figures show that the spacious vortex observed in the sea surface off the southwest slope April 29 to May 5 had been pushed up against the edge of the Bank by a force acting

FIG. 54.—Set II. Direction and velocity of the currents

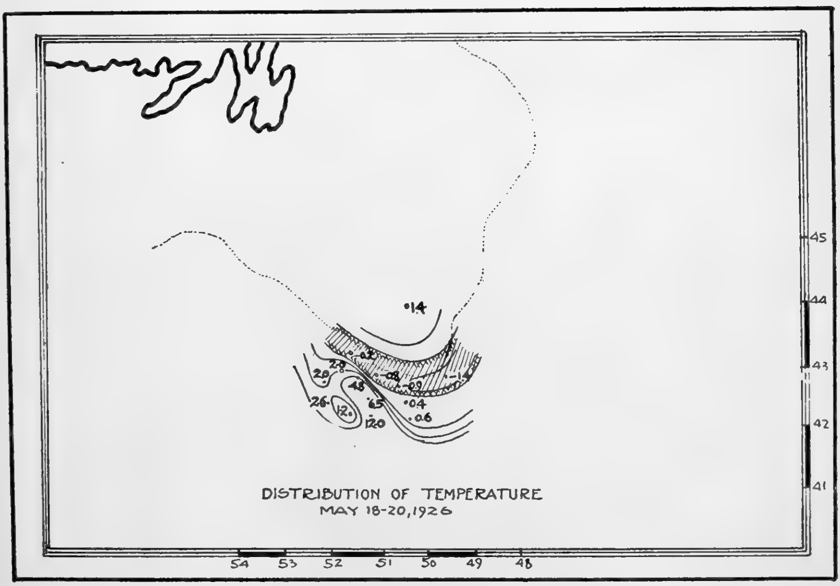

FIG. 55.—Set II. Distribution of cold and warm water

from offshore to the southwest, and this action, moreover, had tended to deepen the vortex by about 10 dynamic centimeters. The steepening of the sides of this hollow had correspondingly intensified the currents around the center so that velocities as high as 1.3 knots per hour are recorded on Figure 54. The distribution of critical temperatures on Figure 55 discloses a wedge of warm water had invaded the locality immediately off the southwest slope from offshore. The western side of the picture shows cold inshore water of northern origin curling around the western extremity of this warm wedge to the southeastward, so that the birth of an anticyclonic

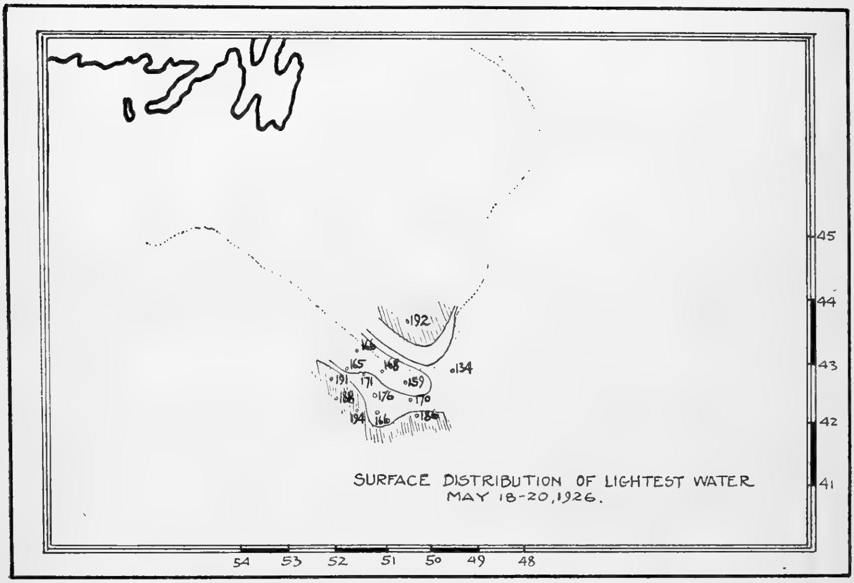

FIG. 56.—Set II. Distribution of light and heavy water on the surface of the sea

rotating eddy is clearly indicated off the southwest slope of the Bank. The lightest water on the surface lay in over the Bank and also offshore at the outer stations, a distribution very similar to that which prevailed two weeks earlier.

SET III

A study of the dynamic topographical map for the period June 25 to 29 shows that the hollow in the sea surface off the southwest slope of the Bank (figs. 49 and 53) had again expanded to about the same form as in early May, except for being slightly more elongate and curling a few miles further to the eastward. A trough extended southward paralleling the east slope of the Bank and at a distance out about 50 miles. The direction and velocity of the currents are shown on Figure 58 as also the drift of two bergs which were sighted

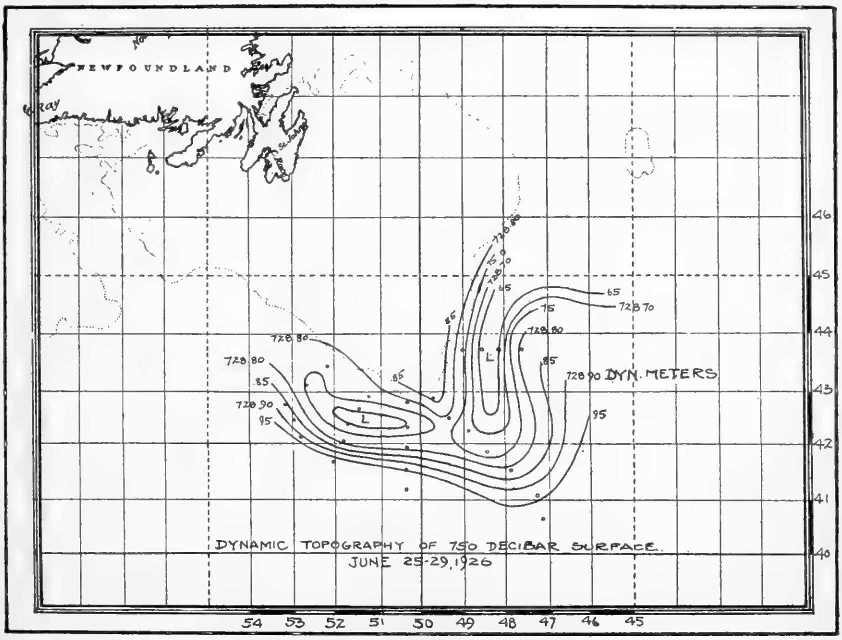

FIG. 57.—Set III. Dynamic topographical map

FIG. 58.—Set III. Direction and velocity of the currents

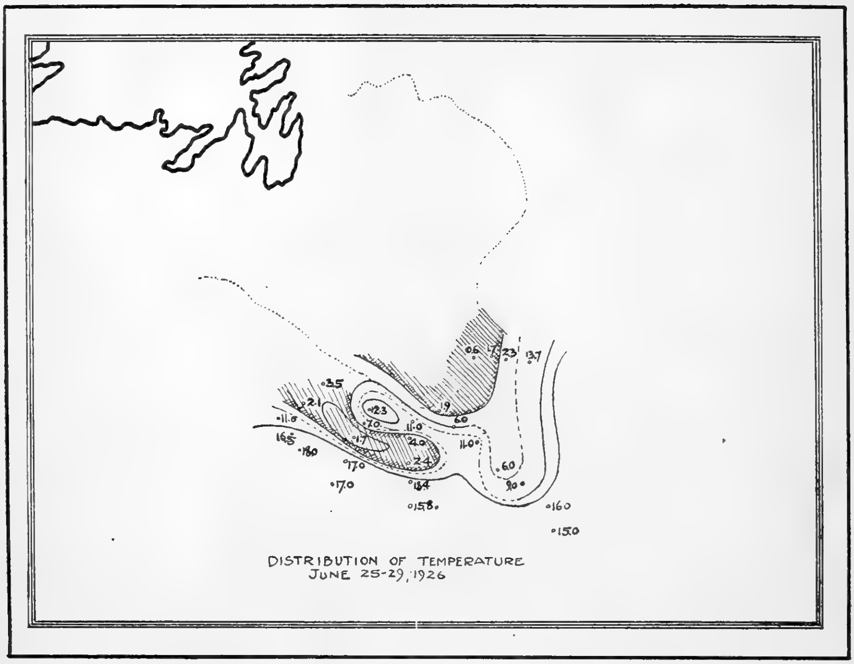

FIG. 59.—Set III. Distribution of cold and warm water

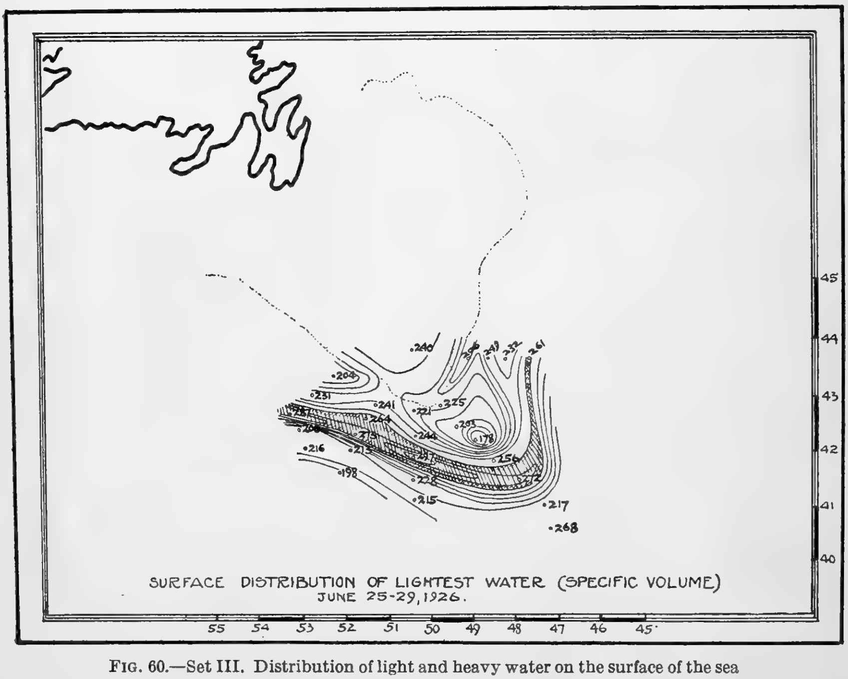

FIG. 60.—Set III. Distribution of light and heavy water on the surface of the sea

in the area at the time. The behavior of the ice conforms as might be expected to the circulation as denoted on the map. The distribution of temperature as plotted on Figure 59 plainly shows that warm water previously mentioned on Figure 55 had worked its way to the northwestward along the Bank slope, while on the other hand cold water from the north curled offshore 150 miles or so westward of the Tail, finally to be carried along in a return stream to the eastward, 30 to 40 miles off the continental edge. A comparison of this map with the two earlier temperature charts, Figures 51 and 55, shows the development of this rotating movement of the warm and cold waters. The lightest surface water (fig. 60) was in the form of a band 25 to 30 miles in width and more or less paralleling the Bank contour about 60 miles offshore. The effect of solar warming of the surface layers during the latter part of June is clearly shown by the increase in values for the specific volumes from those collected for May. (Fig. 52.)

SUMMARY

The work this year marks the first attempt at dynamic calculation of ocean currents on board a surveying vessel immediately following the collection of the data and also the employing of such information at once for the benefit of passing ships. The three sets of observations (figs. 49, 53, and 57) permit us to follow the changes that took place in the circulation around the Tail of the Bank from April 29 to June 30. First, we may regard the circulation as found by the earliest survey as more or less characteristic of the waters around the Tail of the Grand Bank. On or about May 15 warm salty water from offshore interrupted this scheme of circulation by pushing in toward the southwest slope and pinching off the flow of Arctic water that normally drifts clockwise around the Atlantic face of the Grand Bank. This movement characterizing the currents in May had slackened before the latter part of June, and the scheme of circulation had returned to what we regard as normal. Except for this unexplained interruption the cold current continually flowed around the Tail and to a variable distance (approximately 150 miles), along the southwest slope where it turned to the eastward, joining the warm current known as the Gulf Stream. This distribution and direction of the currents tended to form a great anticyclonic eddy off the southwest slope of the Grand Bank.

RELIABILITY OF CURRENT MAPS

One of the problems upon which we wished to gain information as a result of the season's work, was the rate of change in direction and velocity of ocean currents, to tell whether one survey a month would serve all practical purposes or whether rapid changes in the circulation would make more frequent surveys necessary. There have been

very little data collected from the ocean which throw much light on this subject. In case we argue from the atmosphere we know that isobaric maps as much as 24 hours old contain little information on the situation for the present. The scheme of oceanic circulation around the Tail of the Bank this season altered quite noticeably within a space of two weeks and then resumed, broadly speaking, its original state, all within the priod of two months. It is hoped that the same plan of oceanographic work introduced in 1926 is continued for a few years so that we shall be in a position to say considerable more on the reliability of current maps with the elapse of time.

DISSIMILARITY BETWEEN DENSITY AND COLD WALLS

The observations in 1926 corroborate earlier ones to the effect that the density of the water around the Grand Bank is usually higher along the zone of contact between the Labrador current and the Gulf Stream than on either side of the latter. But this density wall does not exactly coincide in location with the zone of most abrupt transition from low to high temperature (the cold wall), but lies as a rule 25 to 35 miles inshore of the latter. Since the density wall unquestionably marks the boundary between the easterly and westerly sets, this discovery means that the drop in the temperature of the surface water near the continental slope does not mark the change in the direction of the current.

LIGHT WATER COLLECTS ON SURFACE OF THE SEA

Evidence has been accumulating that there is a prevailing tendency for relatively light water to collect on the surface of the sea immediately over the belt of the heaviest subsurface water, represented by the density wall; this has been observed in the profiles of every ice season since 1922, so it must be more than a coincidence.

DRIFT OF BERGS CHECKED WITH CALCULATED CURRENTS

We were handicapped this year by fog in comparing the drift of the bergs with the currents calculated and plotted, but the few examples obtained have been found to harmonize. (Fig. 21, p. 73.) The fact that there were few opportunities to make comparisons in the case of specific bergs ought not to be interpreted as detracting from the value of the three sets of illustrations represented by Figures 49, 53, and 57, all of which were continually consulted by those in charge of maneuvering the patrol ships.

THE ELECTRIC SALINITY TESTER

The ice-patrol bulletins for 1924 and 1925 (Nos. 12 and 13) contain sections [1, 2] devoted to the description and method of operation of the electric apparatus for measuring the conductivity of sea water, providing a ready means of determining the salinity of water samples on shipboard. The United States Bureau of Standards constructed one such apparatus, which was first placed in successful operation the season of 1924, when some 600 odd samples of sea water were tested. Concurrent with the progressive scientific program laid down for the 1926 patrol, which attempts to follow the drift of icebergs by keeping an up-to-date current map on board the patrol ship, it became necessary to provide both ships with the apparatus, instead of one as in the past. Salinity determinations during the season of 1926 were thus made immediately after occupying each station and thus we were able to compute the dynamic value, and so to construct a current map on the spot. The new salinity tester was constructed with the cooperation of the Bureau of Standards in time for installation and calibration on board the *Tampa* before she sailed in March. The old set was placed on board the *Modoc*, and both machines, it ought to be added, are alike in detail. A total of about 537 salinity determinations were made during the season of 1926, and no difficulties were experienced with the functioning of the apparatus. A conversion table of scale readings to salinities follows, for use in the operation of these or similar sets in the future.

The scale range of the instrument readings it will be noted extends from 0 to 800. Readings higher than 800 are obtainable by continuing the graph of salinities plotted against instrument readings and checked occasionally by an actual test of a sample of known salinity within the discussed range.

A table of scale readings of the electric salinity tester with the corresponding values of salinity is shown herewith:

Reading	Salinity	Reading	Salinity	Reading	Salinity	Reading	Salinity	Reading	Salinity
0	28.820	10	28.895	20	28.977	30	29.060	40	29.145
1	28.825	11	28.900	21	28.985	31	29.070	41	29.154
2	28.835	12	28.910	22	28.993	32	29.080	42	29.163
3	28.845	13	28.920	23	29.000	33	29.088	43	29.170
4	28.850	14	28.925	24	29.010	34	29.095	44	29.180

PLATE I..—ARCTIC FIELD ICE WHICH HAS ITS SOURCE NORTHWARD IN HUDSON STRAIT AND BAFFIN BAY. IT REACHES ITS MAXIMUM IN THE GRAND BANKS REGION DURING MARCH AND APRIL, AND IS RARELY FOUND SOUTH OF BELLE ISLE AFTER THE MONTH OF MAY. THIS PARTICULAR FIELD EAST WAS SIGHTED BY THE "TAMPA," MAY 6, ABOUT 120 MILES OF ST. JOHNS, NEWFOUNDLAND

PLATE II.—A GREAT NUMBER OF BERGS THAT WERE SIGHTED BY THE "TAMPA," MAY 6, 1927. MORE THAN 70 WERE IN SIGHT FROM THE BRIDGE AT ONE TIME

THE INTERNATIONAL ICE PATROL

1927

The international ice patrol for the season of 1927 was carried on by the United States Coast Guard cutters *Modoc* and *Tampa;* the former was in command of Commander W. H. Munter and the latter was in command of Commander Thomas M. Molloy. The Coast Guard cutter *Mojave*, with headquarters at Boston, Mass., was designated the standby vessel. While on patrol, the *Tampa* and *Modoc* based temporarily at Halifax, Nova Scotia, the two vessels making alternate cruises of about 15 days in the ice regions, and the 15 days being exclusive of the time occupied in going to and from the base. Commander Munter was the commander of the ice patrol, and Lieutenant Commander Edward H. Smith was detailed to assist and advise the commanding officers while they were in the ice regions and to compile data and information for the annual report.

The duties and scientific work carried on by the ice patrol were, in general, similar to the practice of the previous season. The primary object of the patrol was to locate by scouting, and radio information, the icebergs and ice fields nearest to, and menacing, the North Atlantic lane routes, and to determine the southerly, easterly, and westerly limits of the ice and to keep in touch with it as it moved southward. Radio broadcast were sent out four times daily giving the whereabouts of this ice and particularly that which was in the immediate vicinity of the North Atlantic lane routes, and ice information was furnished by radio at any time to any ship with which the patrol vessel could communicate. In order that an intelligent service of the highest order be rendered to shipping, an oceanographic program was carried out to afford the vessel on patrol with a practical, up-to-date current map of the critical, infested ice area under surveillance, and scientific studies and observations made bearing upon ice conditions and ice movements. The oceanographic and scientific work being supportive, and secondary in importance, was so arranged that it would not hamper the ice patrol in its primary function of ice scouting.

The *Tampa* inaugurated the patrol on March 22 and from that date until June 25 there was either that vessel or the *Modoc* continuously on guard in the ice regions.

Beside the ice-patrol service, the safety of shipping is further guaranteed by mutually agreed upon steamship tracks past the ice regions, prescribed by the North Atlantic track agreement. They

are designated by letters, A, B, C, D, E, and F. Tracks A, B, C, and D refer to routes between the United States and Europe, and they all run near, or south of, the Tail of the Grand Banks. Tracks C are known as winter-time courses, and they are in force from the 1st of September to the 1st of February, when the United States-Europe tracks are shifted southward to letter B, where in turn they remain during a normal ice season until September 1. If ice, however, drifts far south during the danger season it is customary, upon recommendation from the International Ice Patrol, to shift tracks B to tracks A, "extra-southerly" for a month or two. The dates of shifting are subject to changes depending mainly upon ice conditions of the particular year.

Tracks E, F (Cape Race track), and Belle Isle tracks refer to routes between Canada and Europe. Tracks E are in force normally from April 11 to May 15. Tracks F are in force from May 15 till opening of the Strait of Belle Isle, about July 1, and these latter continue in effect until the closing of navigation on the Gulf of St. Lawrence.

It is clearly seen from the foregoing that prior to April 11 all prescribed steamship tracks cross the ice regions near or south of the Tail of the Grand Banks, but after that date the Canadian-European routes separate from those of the United States-Europe, so that during the season when bergs menace navigation in greatest numbers there are two paths of ocean travel separated by a distance of about 400 miles. It ought to be mentioned that since the ice patrol was originally established the volume of traffic on the Canada-Europe routes (those are the ones that cross the ice regions during the iceberg season) has increased many fold.

CRUISE REPORTS

THE FIRST CRUISE, "TAMPA," MARCH 22 TO APRIL 9, 1927

In accordance with headquarters telegram of March 19, 1927, the *Tampa* sailed at 1.41 in the afternoon of March 22 for the Grand Banks. During the second day at sea a message was received from the United States Hydrographic Office, Washington, stating that trans-Atlantic tracks "B" would remain in force until further notice. It took us an unusually long time—six days—this year to make the passage to the ice regions, and this slow progress was due to the presence of an area of high pressure located over Newfoundland. Our track situated on the southern side of this wind system gave us head winds the entire passage. On the 28th we sent messages to all adjacent radio stations requesting their cooperation and informing them that we were inaugurating the ice-patrol service for 1927. The routine broadcast was dispatched to all ships and also the evening report to the Hydrographic Office, Washington.

A search for ice was instituted the morning of the 29th and also on the 30th. Somewhat north of the forty-third parallel along the eastern slope of the Grand Banks we sighted a total of three small bergs and one growler. The *Tampa* remained near this ice and drifting with it to the southward during the remaining two days of the month. From April 1 to 6 the time was spent searching for ice around the Tail of the Bank and along the eastern slope, or drifting near small bergs or growlers. The weather was exceptionally good during these days; for example, on March 26 there was not a cloud in the sky the entire day and the sea was very calm, two conditions truly remarkable for this time of the season.

We planned during the last few days of the cruise to begin a current survey along the eastern side of the Bank and carry the observations to the westward, and when the relief ship was met, giving her the remaining half of the oceanographic work to perform. This program was carried out and we met the *Modoc* about 150 miles west of the Tail of the Grand Banks on the eighth day of the month where the relief was effected and the *Tampa* stood toward Halifax.

The weather this cruise was noticeably fair and much better by far than that we encountered during the early part of the patrol last year. There were a few intervals of low visibility but no fog. During the cruise we received a total of 630 reports from passing vessels on the subject of their surface water temperatures; three vessels

were supplied with special ice information; two with track information; 125 ice reports were received. A total of six small icebergs was sighted.

THE SECOND CRUISE, "MODOC," APRIL 9 TO 24, 1927

The 9th and 10th instants were sufficient to complete the oceanographic survey, and when the *Modoc* had arrived off the Tail of the Banks the program was then turned to scouting along the eastern side of the Bank for ice. About 4 o'clock the afternoon of the 11th a berg was sighted in a position which proved to be 20 miles south of the Bank and we stood by it for the remainder of the day. During the next two days this berg drifted to the westward and then northwestward and finally into shoal water on the Bank itself. When we left it, on the 15th, it had not changed position for two consecutive days, and this, coupled with the fact that it was very much reduced in size, caused us to leave and begin searching northward for other menaces.

About 3 o'clock in the afternoon of the 16th the *Modoc* sighted the largest berg that had been seen this season, and while lying near this ice we received our first intimation that the warm, off-shore, countercurrent was pressing in toward the Bank this year unusually far. In fact, this large berg beside which we had stopped, it was plain to see, was in this countercurrent although its position was barely 40 miles outside the 100-fathom curve. It was extraordinarily calm that evening and the demarkation between the two currents could easily be seen stretched about 2 miles to the westward of us, and running in a direction more or less parallel to the trend of the slope. Easter Sunday the wind increased to gale force and in the storm we lost sight of our quarry but the fact that this ice was known to be in the warm countercurrent was more or less reassuring of a rapid disintegration. The large berg was reported for the last time on the 20th about 30 miles to the northeastward of our position surrounded by several growlers, showing that it was breaking up rapidly.

Now the cruise was drawing near its close, so we followed a program similar to the one used on the *Tampa*—taking oceanographic stations on the slope and working around to the westward. The *Tampa* was met on the morning of the 24th of April and the patrol duty turned over to her.

During this cruise we received several reports of field ice and icebergs to the northward. The field ice on the northern edge of the Bank was, of course, Arctic in origin, but the field which extended southward to a point 25 miles north of Sable Island came from the St. Lawrence. There were very few ships on the tracks which led across the northern part of the Banks. The initial vessel bound for the Gulf this year is believed to have been the steamship *Bolingbroke*, which

reported her position on track "E" April 19. The same day we were informed that the Canadian ice patrol ship *Mikula* was now on her station near Cabot Straits.

The outstanding feature of the cruise was the inshore distribution of the ice as it was carried southward. Where it is usually transported in the heart of the current along the 100-fathom contour of the continental edge, this year it was moving southward 15 to 25 miles inshore of that zone. Such a condition is attributed to the warm Atlantic waters pressed in against the continental slope combined with an abnormal prevalence of easterly and northeasterly winds. We received 840 water temperature reports, 89 ice reports, sighted 7 icebergs, gave 13 ships special ice information, and requested 27 others to acknowledge for the evening broadcast, as it was observed that their courses were taking them dangerously close to ice.

THE THIRD CRUISE, "TAMPA," APRIL 24 TO MAY 8, 1927

The current survey begun on the *Modoc* was completed in two days, and the same evening, the 25th, a report was received regarding an iceberg about 100 miles due west of the Tail, in a position which we had passed over in the morning. This ice was missed probably because of the poor visibility, it being hazy and foggy all the previous day. We headed toward the reported locality, of course, and fortunately sighted the berg dead ahead at 7 o'clock on the morning of the 26th. It was hard to account for this ice having followed the usual path toward the Tail, and the only conclusion tenable was that it must have drifted diagonally across the Bank, southwestward. Such an opinion was supported, furthermore, by the fact that on the 21st, five days previous, the *Modoc* had sighted a berg about 40 miles to the northeast of this position, to which the berg we were standing by bore a close resemblance. We drifted with this ice for the next three days and during that time it constantly melted and finally completely broke up, but did not move far away from the spot at which it was originally sighted. More than passing interest attaches to this ice because it happened to be the last berg for the season of 1927 to drift so far southward and, moreover, proved to be, out of all the bergs for the season, the one which drifted nearest to the westbound steamship tracks "B;" a distance of 70 miles. (See fig. 28.)

Fog and storms interrupted the ice-searching program for the next few days and it was not until the 3d of May that the *Tampa*, at 13 knots speed, resumed scouting along the eastern side of the Bank. There followed several days of clear weather during which time we pushed home the search and covered the cold current along the entire eastern side of the Bank, thence westward to the coast of Newfoundland. May 6, when about 100 miles east of St. Johns, Newfoundland,

the *Tampa* sighted a great quantity of ice; approximately 100 bergs and several ice fields during the day (see Pl. II). This is the largest number of bergs, according to records, ever sighted at one time by the patrol ship around the Grand Bank.

The *Modoc* was met on the 8th of May near Cape Race and the patrol duty turned over to her. There were 1,040 sea-water temperature reports received, 82 reports of ice, about 120 bergs sighted, 6 steamships given special ice information upon request, and 23 vessels were asked to acknowledge for our evening ice broadcasts.

THE FOURTH CRUISE, "MODOC," MAY 8 TO 23, 1927

The *Modoc* proceeded to the eastern side of the Grand Bank, arriving there on the 10th of May, and after locating the southernmost bergs on the slope just north of the forty-sixth parallel, prepared to take a line of oceanographic stations off to the eastward, the beginning of a current survey. We were handicapped in this work on account of the drum of the new oceanographic hoist the flange head of which broke in two after taking the second station. The second hoist was quickly installed, however, by the crew working most all of that night, and in the morning we were ready to go ahead again.

A message was received from headquarters early the morning of the 11th requesting the *Modoc* to keep a bright lookout for an airplane on its nonstop flight from New York to Paris, the *Modoc* taking a position about 60 miles due south of the Tail in the reported line of flight. As the time of flying was postponed on account of bad weather conditions prevailing in the North Atlantic, we took advantage of the delay to continue with the current survey, running a line of stations normal to the slope and southward to this forementioned position, thus the time was spent from May 11 to the 20th. During this period, by the way, almost continuous south winds and fog prevailed. No ice was sighted and there were very few reports from ships regarding this subject. The few bergs that were observed were distributed on the northern part of the Bank; some of the same ice which we had previously sighted May 6 on the *Tampa*.

The last few days of the cruise clear weather set in and the patrol ship was cruised northward along the eastern slope of the Bank, searching for ice. Only one berg was sighted and that on the last day of the cruise, it being found just north of the forty-sixth parallel in the shoal water inside the 50-fathom curve.

Following is a summary of the ice patrol work during the cruise: Sea-water temperatures received, 1,100; ice reports received, 42; vessels requested to acknowledge for our broadcasts, 10; special ice information given, 9; and bergs sighted, 1.

THE FIFTH CRUISE, "TAMPA," MAY 24 TO JUNE 8, 1927

After relieving the *Modoc*, about 200 miles east of Cape Race, we stood to the northward and began searching at daylight along the eastern slope of the Bank. Visibility became poor at noontime on account of snow squalls, but before it shut in thick a large berg was seen not far away beside which we stopped for the night. It was estimated to-day that there was a total of 40 bergs and 60 growlers scattered along both sides of the Cape Race track from latitude 48° 00′, longitude 48° 30′, and all the way to Cape Race. The ice was especially concentrated in the vicinity of latitude 47° 30′, and longitude 50° 20′.

The next day, May 25, we experienced one of the most severe gales of the season and there was little else to be done but drift near the berg of yesterday. When the gale abated we searched in the vicinity and located a total of six bergs all strung along out the northeastern slope of the Bank and drifting southward at the rate of 1.2 knots per hour.

At this time we began an oceanographic survey which extended southward along the Bank and had for its purpose the mapping of the position of the two currents because it was being quite important at this time to have on board the patrol ship information regarding the probable path which the group of icebergs mentioned above would take. We were successful in this plan and the behavior of the ice followed closely to the position of the current as calculated. (See fig. 46, p. 86.) One iceberg of this group which succeeded in hugging close to the edge of the Bank, and thereby drifting south the farthest, was sighted on the 1st of June in latitude 44° 55′, longitude 48° 25′.

June 2 was foggy but it cleared the 3d, and remained good visibility the 4th and 5th, permitting the patrol vessel to make a fairly thorough search of the eastern and northern slopes of the Grand Bank. Many bergs were found in the locality which the *Tampa*, a month prior to this date, sighted 70 bergs at one time from the bridge, but now the number had been very much reduced due to melting and disintegration.

One of the most interesting events of the cruise occurred early the morning of the 6th when we intercepted a message from Cape Race radio station stating that a French fishing vessel had stranded about 3 miles west of the station. The *Tampa* headed toward Cape Race, 129 miles away, and full speed was ordered in the hopes that there would be an opportunity to save this vessel. An untimely arrival of a low-pressure area north of Newfoundland brought a southerly gale this same day, and at the same time a choppy sea made up, which soon made short work of this unfortunate vessel stranded on a rocky, lee shore. We were forced to give up the attempt of rescue and made

the best use possible of the remaining time of this cruise to locate ice in the vicinity of Cape Race. The patrol work during the cruise consisted of receiving 1,100 water-temperature reports, 82 ice reports, 18 vessels were asked to acknowledge for evening broadcasts, 14 special ice-information reports were given, and a total of about 40 bergs sighted.

THE SIXTH CRUISE, "MODOC," JUNE 8 TO 23, 1927

Our first task was to search eastward along the northern slope of the Bank about 15 miles north of the track made by the *Tampa* on her course to the westward a few days ago. The search was handicapped to a great extent by patches of fog and low visibility, but, nevertheless, we sighted about 10 bergs and several growlers while on this work, which was concluded on the 10th instant. Advantage was also taken of several steamers on courses more or less paralleling ours to the north and south, to estimate that there was a total of 68 bergs this date south of the forty-eighth parallel.

The final oceanographic survey for 1927 was begun on June 10 and carried out, but for a single interruption, the remainder of the time which the *Modoc* had the patrol duty. During the course of nine days we covered the largest area which had ever been accomplished on patrol, namely, from the forty-eighth parallel south to the Tail, and from the Grand Bank eastward to Flemish Cap. This survey was timely and proved to be of inestimable value toward forming an accurate opinion, and resulting recommendation, for the discontinuance of ice patrol. This is an example of the value attached to scientific investigations of the currents around the Grand Banks. Never before have patrol officials been so well informed and been able to express such an intelligent prediction as to the status of the ice menace as they were at the close of the season of 1927.

On the 13th instant the *Modoc's* current survey was interrupted for two days by an urgent call for medical assistance from the steamer *Conness Peak*, then well out in mid-Atlantic. The *Modoc* on this mission, without doubt, was able to save the life of the second officer who had received serious injuries as the result of a fall.

June 24 we met the *Tampa* about 150 miles west of the Tail of the Bank, and, after a conference between the two ships, the commander, international ice patrol, forwarded a dispatch to headquarters which contained a résumé of the principle features of the ice season, the survey of the present situation, and his recommendation for the discontinuance of the patrol.

The following is a summary of the work performed during the sixth cruise: 848 water-temperature reports received, 77 ice reports received, 13 vessels were asked to acknowledge for the evening broadcasts, 10 ships were given special ice information, and 36 icebergs sighted.

THE SEVENTH CRUISE, "TAMPA," JUNE 24 TO 25, 1927

We began work on a survey of the currents around the Tail of the Bank and along the southwest slope, but this work was abandoned upon the receipt of orders from Washington to discontinue ice patrol and return to home stations. Messages of thanks for cooperation were sent to all neighboring radio stations as well as to the steamships which happened to be in the ice regions.

RADIO COMMUNICATIONS

One of the most important features of the ice patrol work is an efficient and consistent performance of radio communication; in fact, the success of the patrol lies to a great extent in correctly accumulating and disseminating the ice and obstruction information. The ice area, moreover, which is kept under surveillance by the patrol ship, is greatly enlarged by the information received over the radio from ships scattered throughout the entire ice regions. The operations of 1927, as in past years, revealed excellent cooperation on the part of the merchant vessels and the shore stations; a spirit which is highly gratifying to the patrol. We desire also to add that the Canadian direction-finding stations, Cape Race commercial radio station, and bordering United States naval radio stations have done all possible to facilitate the patrol radio communications.

We are impressed, when making a survey of the radio work of 1927, with the fact that schedules between the United States naval radio stations and the patrol ship were maintained more consistently than ever before. This condition is attributed, first, to the higher power used this year by naval stations, and, second, to the personal cooperation shown by the individual operators both ashore and afloat. In previous years, too, ship-to-shore communication has often been interrupted by summer-time static conditions, but this difficulty in 1927 was seldom encountered, and then for short periods only.

The radio equipment carried on board the patrol vessels was practically the same as that used in 1926. (See Bulletin No. 15.) The high-frequency experimental receiver was replaced by a new type called the "R.G." high-frequency receiver, the latter being a later model, better constructed, possessing a wider range of frequencies, and also being more sensitive than the older receiver to weak signals. The R.G. receiver proved itself far superior both in ease of control and signal amplification than any of the former types of apparatus. The XA 500-watt high-frequency transmitter was the same as that used last year with the exception of several alterations made at the Navy experimental laboratory, Bellevue, Md., during the winter of 1926–27. Improvements included easier adjustment on specified frequencies, and installation of a plate overload relay, in order that damage would not result because of sudden rise of plate voltage. The only trouble experienced with any of the apparatus during the patrol occurred on board the *Tampa*, where a variable ground developed in the high-voltage leads of the 2,500-volt main radio motor

generator. Both the T–2 2-kilowatt tube transmitter and the XA 500-watt high-frequency set, in consequence, were out of commission for three days until repairs were completed. The *Tampa*, fortunately, carried spare generator parts on board for just such an emergency. The trouble caused no delay, however, in the reception of ship reports, because a separate power supply is used in connection with the spark transmitter for the purpose of ship-to-ship communication.

The radio electrician in charge of ice patrol communications, and detailed to remain continuously at sea, was taken seriously ill during the first part of the ice season, and it was necessary for him to return to Boston for treatment. The vacancy thus created was filled by a radio man, first class, assigned from the personnel of the *Tampa*, who transferred from ship to ship for the remainder of the patrol.

The amount of ice patrol traffic handled by radio is always interesting and indicative of the importance of this work to the success of the patrol. There were approximately 5,548 reports received from passing steamers concerning their position, course, speed, and sea-water temperatures. A total of 380 official messages were transmitted to Washington, and 84 were received. It is estimated that a total of 274,407 words were handled during the season of 1927 (see p. 15).

There is appended herewith a schedule giving the times at which messages were received and sent by the patrol vessel. This schedule was adopted after several preliminary tests in 1926, and, as outlined here, was found quite satisfactory for the season of 1927.

(All times are seventy-fifth meridian)

0600. Ice broadcast (spark); call on 600 meters, then send twice on 706 meters with a 2-minute interval.

0700. Ice broadcast (continuous wave); call on 600 meters, then send twice on 1,713 meters with a 2-minute interval.

0730. Clear all ship-to-shore traffic with Washington (NAA). Ice patrol using 410 kilocycles.

0800. Clear all ship-to-shore traffic with Bar Harbor (NBD) in case the 0730 schedule fails. Ice patrol using 1,713 meters.

0915. Copy Cape Race weather and obstruction broadcast.

1030. Copy Arlington weather broadcast.

1200. Copy time signals and ice patrol traffic from Arlington (NAA).

1800. Ice broadcast (spark); call on 600 meters, then send twice on 706 meters with a 2-minute interval.

1900. Ice broadcast (continuous wave); call on 600 meters, then send twice on 1,713 meters with a 2-minute interval.

1930. Clear all ship-to-shore traffic with Washington (NAA) on high frequency.

2000. Clear all ship-to-shore traffic with Bar Harbor (NBD) in case the 1930 schedule fails. Ice patrol using 1,713 meters.

2115. Copy Cape Race weather broadcast.

2200. Copy time signals and ice patrol traffic from Arlington (NAA).

2230. Copy weather broadcast from Arlington (NAA).

SUMMARY REPORT OF COMMANDER INTERNATIONAL ICE PATROL

The ice patrol was inaugurated March 22, when the *Tampa* sailed from Boston. The *Modoc* left Boston in sufficient time to relieve the *Tampa* after she had been on duty for 15 days. These two Coast Guard cutters then alternated on duty throughout the remainder of the season, one of the vessels being continuously on guard in the ice regions. This work required a total of seven cruises, and Halifax, Nova Scotia, was made the port of call at which fuel and supplies were obtained. The patrol service was discontinued on June 25 when a dispatch from headquarters directed the vessels to return to their respective stations. The total period during which the vessels were on guard was 95 days—3 days short of the time in 1926.

The patrol work has been for some few years regarded as having two general features: First, and of primary importance, is the actual search carried on by the patrol; the collecting of all the ice reports from passing vessels; and the dissemination of this information four times daily. Second only to the foregoing is the scientific work which in late years has centered on frequent surveys of the currents which transport the ice about to various menacing positions.

We wish in referring to the practicable work this year to briefly summarize the general distribution of ice and its behavior. A discussion of the subject is carried in greater detail under the section devoted to ice observation (p. 52), to which the reader's attention is invited. As early as March 11, a prediction was made in accordance with an iceberg forecasting equation (see Bull. No. 15, p. 48) that 396 bergs would drift south of Newfoundland for the season of 1927. It developed actually that there was slightly more ice during the spring of 1927 than occurs in a normal year about 380, and this agreement between fact and prediction lends added confidence to such a method of iceberg forecasting for future years. Although the number of bergs south of Newfoundland (below the forty-eighth parallel), was slightly above the average, the amount of ice around the Tail of the Bank and near the United States-Europe steamship tracks was remarkably deficient. The interference in the normal distribution is attributed to two factors, (1) the predominance of northeasterly winds during the early part of the season and, (2) the unusual inshore invasion of warm counter oceanic currents. The discussion of these features in considerable detail will be found under

sections devoted to weather and to oceanography. There were approximately 365 bergs south of Newfoundland during the four months March to June but there was the astonishingly meager number of only eight bergs south of the forty-fifth parallel during this same period. The greatest number of bergs around the Tail at any time occurred the first week in April when there were four small ones there, and the patrol kept these under surveillance until they finally melted. The last berg to appear off the Tail did so April 28, and thereafter these waters were clear of ice during May and June. In fact with the exception of a small berg which drifted 10 miles south of the forty-fourth parallel on June 8, there was no ice south of the forty-fifth parallel after April 30.

The fact that the total number of bergs was slightly above normal, and that the waters south of the forty-fifth parallel remained so free of ice, naturally concentrated the bergs on the northern part of the Bank where as many as 100 to 150 accumulated the first week in June. They disintegrated quite rapidly, however, because when the patrol vessel left, June 25, it was estimated that there were few more than 15 bergs south of Newfoundland.

The weather during the ice season of 1927 was in general very good. Both the *Tampa* and the *Modoc* on their first cruises experienced unusually fine weather at a time in early season when cyclonic disturbances are often numerous and gradients are correspondingly steep. It was recalled that in the early season of 1926 the vessels encountered continual gales for the first month of the patrol. The second feature was the change from wintertime to summertime conditions with attending southerly winds, an event which was first noticed May 11, contemporary with the first long spell of fog and low visibility. The usual stagnation in the movement of low-pressure and high-pressure areas, and the flattening out of gradients, was not so apparent this season as it has been in some years. Several times during the month of June, for example, well developed "highs" and "lows" moved across the ice regions with unseasonable velocity.

Scientific work this year was carried on under the supervision of Lieutenant Commander Smith, who followed the same general policies that were instituted by the ice patrol board in 1926. A discussion of the weather, the distribution of the ice, and the scheme of oceanic circulation that prevailed in the ice regions, is carried under the respective sections devoted to weather, ice observation, and oceanography. The absence of ice near the steamship lanes in 1927 afforded opportunity for more current observations than ever before, and consequently, the patrol ship was able to foresee more clearly than ever in 1927, the developments in the ice situation. Attention is particularly invited to the current map covering the last few weeks

72092—27——2

of the patrol (see fig. 50, p. 90), during which time the waters of the entire eastern side of the Grand Banks were mapped. This timely information enabled the patrol to forward to Washington officials an intelligent and accurate recommendation regarding the safety of the trans-Atlantic tracks. The drift of the ice and the stream lines of the currents, as calculated from the station data, agreed very closely. The methods employed in determining the direction and velocity of the currents around the Grand Bank, which are described in Bulletin No. 14, 1925, appear very feasible and the results in 1927 certainly threw an intelligent light upon the probable movements of the ice, a subject which naturally is of inestimable value to those in charge of the patrol work.

The patrol ships had on board practically the same outfits as carried in 1926 with the exception of a larger number of spare oceanographic instruments. The installation of new electric hoists for lowering and hoisting the water bottles was a great improvement which shortened the time spent at stations by almost one-half. The policy begun in 1926 of carrying out a survey of the bottom contour whenever opportunity afforded was continued by the *Tampa* in 1927, and about 435 sonic soundings were obtained in this manner. The sonic apparatus is also of invaluable assistance in locating the position of the patrol ships, and the ice sighted, during the protracted periods of cloudy and foggy weather around the Banks. The radio apparatus functioned quite satisfactorily this year with the exception of three days when the *Tampa's* main motor radio generator developed a ground. The trouble was located, however, and by working night and day the patrol ship was soon back on radio schedules. The breakdown, it should be added, did not affect the set which is used to communicate with passing vessels, as the spark set is on a separate generating circuit.

About 450 steamships are known to have taken advantage of the service provided by the ice patrol this year, and no doubt there were many more, that also listened in for the daily broadcasts. We made a few inquiries as to how far the ice patrol reports were picked up, and what the general policy was among the steamers regarding listening in for the ice broadcasts. The replies indicated that radio contact with the patrol was usually made at a distance of about 450 miles east and west of the Grand Banks; also that the commercial radio operators were given standing orders to copy the broadcasts at all times when within this range, giving the messages priority over all other traffic. The following list is submitted in order that the reader may obtain an idea of the service which is being furnished the ships of many nations. The masters of these vessels have been thanked, by letter, by the chairman of the ice patrol board.

Belgian	4	Dutch	30	Italian	17	Spanish	3
British	150	French	7	Japanese	3	Swedish	25
Canadian	36	German	12	Norwegian	32	United States	104
Danish	17	Greek	2	Portuguese	1		

A summary of the work performed, the dissemination of the information, and other miscellaneous business handled by the patrol for 1927 follows:

Washington official messages	424
Daily routine broadcasts	380
Special broadcasts (during fog)	8
Ice information to certain vessels, special	91
Special ice information requested	55
Position reports requested	6
Track information requested	2
Weather reports received	464
Water temperature reports received	5, 548
Ice reports received:	
Steamships	380
Cape Race radio station	107
Medical treatment by radio	3
Violation of steamship tracks reported	1
Radio compass bearings received	291
Words handled by radio	274, 407

As in previous years, the cooperation received from passing ships was generous and indicative of a sincere appreciation of the service which is being financially supported by international contribution. The commander of the ice patrol takes this opportunity to thank all those who assisted in making this past season's work so successful.

TABLE OF ICE AND OTHER OBSTRUCTIONS—1927

Date	No.	Reported by—	Position: Latitude, north	Position: Longitude, west	Nature of ice or obstruction
			° ′	° ′	
Jan. 1	1	Cape Race (station)	47 02	47 47	Berg.
1	2	do	48 02	47 49	Do.
1	3	do	48 04	51 23	Do.
1	4	do	47 43	50 11	Small berg and growler.
1	5	do	47 42	46 22	Growler.
Feb. 8	6	do	20 miles East Bull Head		Berg.
10	7	do	47 43	48 41	Small berg.
10	8	Oxonian	45 52	57 20	Thick field ice.
12	9	Cape Race (station)	47 00	47 41	Large berg.
13	10	Incemore	46 07	47 12	Berg.
13	11	Cape Race (station)	46 40	47 42	Do.
13	12	do	46 35	47 30	Small berg.
13	13	do	46 06	47 12	Berg, same as 10.
13	14	do	45 58	47 29	Do.
15	15	do	46 02	46 25	Do.
15	16	do	44 56 to 45 00	60 00 to 60 06	Patches of field ice.
19	17	do	48 20 to 47 50	50 00 to 50 05	Field ice.
19	18	do	47 50	50 25	Berg.
19	19	do	46 55	61 25	Field ice.
20	20	do	46 30	53 17	Berg and heavy slob ice.
21	21	Stockholm	44 22	62 41	Large growlers.
21	22	Cape Race (station)	47 05	49 12	Small berg.
22	23	do	46 45 to 46 30	51 17 to 52 10	Slob ice in all directions.
22	24	do	46 05	49 12	Small berg.
24	25	do	46 34	52 23	Large berg, same as 20.
24	26	do	2 miles S. E. Renews Rock		Do.
25	27	do	47 31 to 47 14	47 48 to 47 36	Field ice and growlers.
25	28	do	46 55	47 23	Field ice and small bergs.
25	29	do	5 miles East Cape Race		Berg.
25	30	Hellig Olav	46 56	47 23	Field ice extending north and south.
26	31	Cape Race (station)	45 22	54 27	Field ice.
26	32	do	46 00	47 30	Field ice extending 10 miles north and south.
26	33	Hellig Olav	45 30 to 45 40	54 00 to 54 35	Field ice, same as 31.
27	34	do	44 52 to 44 46	60 10 to 60 50	Heavy field ice, same as 16.
28	35	Cape Race (station)	46 25	47 15	Growlers and field ice.
28	36	do	46 50	47 30	Drift ice.
Mar. 2	37	do	46 12	47 13	Small berg and northward field ice.
6	38	do	48 10	48 00	Drift ice.
7	39	do	12 miles S. W.		Tall berg and light slob ice.
10	40	Vela	47 00	50 30	100 miles of field ice to the eastward.
13	41	Cape Race (station)	47 00	47 00	Large berg.
14	42	do	48 30	49 30	Large berg and field ice.
14	43	do	46 36	46 48	Do.
14	44	do	46 47	48 05	Two small bergs and some growlers.
14	45	do	47 35	47 26	Large berg.
18	46	do	47 05	46 59	Do.
18	47	do	47 58 to 46 50	48 45 to 46 47	Ice field.
19	48	do	46 30	46 46	Berg.
19	49	do	46 20	45 50	Do.
19	50	do	46 30	45 54	Dangerous growlers and small pieces.

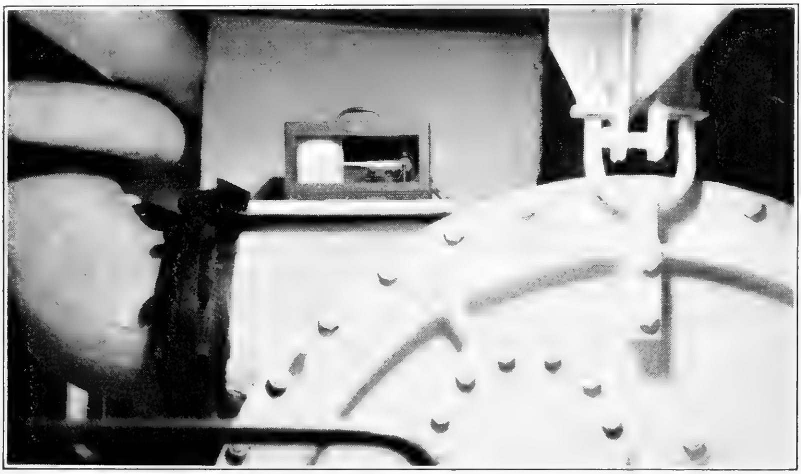

PLATE III.—THERE IS NOW INSTALLED IN THE CONDENSER INTAKE PIPE OF BOTH ICE PATROL SHIPS A SEA-WATER THERMOGRAPH, WHICH REGISTERS CONTINUOUSLY THE TEMPERATURE OF THE SURFACE LAYER THROUGH WHICH THE VESSEL PASSES

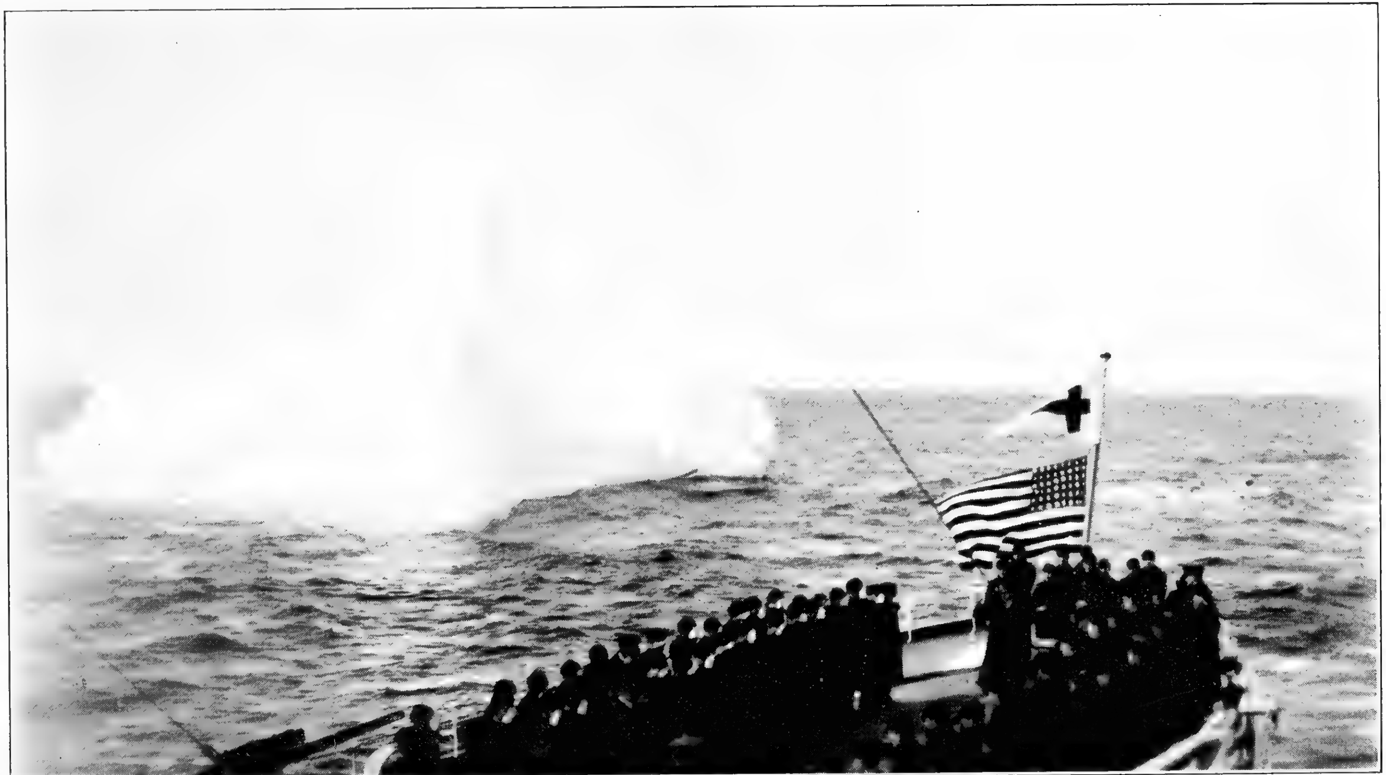

PLATE IV.—DIVINE SERVICES HELD ON THE "MODOC," APRIL 14, 1927, UPON THE FIFTEENTH ANNIVERSARY OF THE SINKING OF THE "TITANIC" WITH THE LOSS OF 1,571 LIVES FOLLOWING A COLLISION WITH AN ICEBERG

WEATHER

Following the arrangement of reports in former years, there is set forth under this section a description of the general weather conditions that were experienced during the ice patrol of 1927. The remarks, which are grouped according to months, are devoted to tracing the general behavior of the high and low pressure systems in the atmosphere as they traveled over the eastern United States and passed out to sea, across the ice regions. Accompanying the monthly remarks is a sketch showing the tracks of the more noteworthy disturbances, and also in other particular instances sketches have been appended. The weather diagram for each month gives at a glance the wind direction and force averaged for every 12 hours; the barograph curve; and the time and duration of fog and low visibility during the month. The geographical position, for which this is a meteorological record, although observed from the patrol ship cruising in the ice regions, can for all practical purposes and interpretations, be taken as latitude 43° 00′ N., longitude 50° 00′ W., the Tail of the Grand Banks. A general description of the two major types of weather which prevail in the ice regions, remarks on the structure of a storm, and iceberg forecasting by means of the weather are all contained in the ice patrol report for 1926 (Bull. No. 15), to which the reader's attention is invited.

MARCH

When the *Tampa* left Boston on March 22, a great mass of cold dry air was spreading east and southeast out of central Canada, across the North Atlantic States, the Maritime Provinces, and out on to the ocean. A center of low pressure retreated before this invasion leaving one vast area of high pressure enveloping the land and ocean to the northward of us. The *Tampa*, because of such a distribution of pressures, experienced continuous easterly winds on her passage to the ice regions. Along the southeastern border of this aforementioned air mass, from March 23 to 26, there traveled a low-pressure disturbance. It was first observed on the meteorological map for March 22 off the coast of the Carolinas, but after that it could not be followed so clearly, due to the scarcity of ship reports from this direction. Its path is shown fairly accurately, however, as track A on Figure 2, the center passing close to the *Tampa* on the morning of the 26th instant, when she was south of Sable Island. The first effects of this storm (a depression of the barograph, see fig. 1) were

observed when the center was about 420 miles from our position. It was then traveling at the approximate rate of 20 miles per hour. Soon after it had passed we got a rapid shift in the winds to a northwesterly direction, which increased three hours later to force 10 of the Beaufort scale.

A second large anticyclone spread across the country and out to sea from the 27th to the close of the month, thus furnishing the

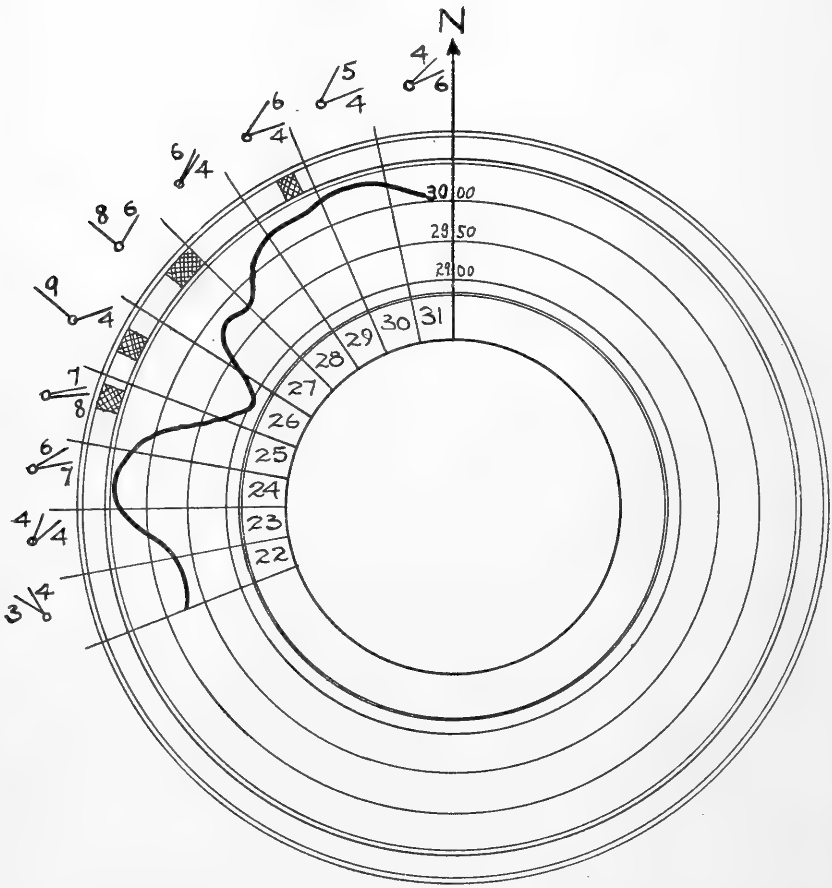

FIG. 1.—March weather diagram. The inner circle gives the day of the month; the next band out contains the record of atmospheric pressure; the next outer one indicates the degree of visibility (crosshatched areas represent low visibility and black areas duration of fog); the outer margin shows the average direction and force of the wind, per 12-hour periods, noon and midnight

Grand Banks with prevailing northeasterly winds and generally fair weather for the end of the month.

Another disturbance from March 29 to April 3, took a path shown as track B on Figure 2. It followed a course farther north than most storms, due to an interposing anticyclone that was lying over the Atlantic States at the time. This situation tended to keep it at a distance from our vicinity, yet on reaching a point near St. Johns, Newfoundland, the depression deepened and thus intensifying, for

about eight hours, April 2, set up a considerable indraught of southerly winds. This brought heavy rains and some low visibility for a

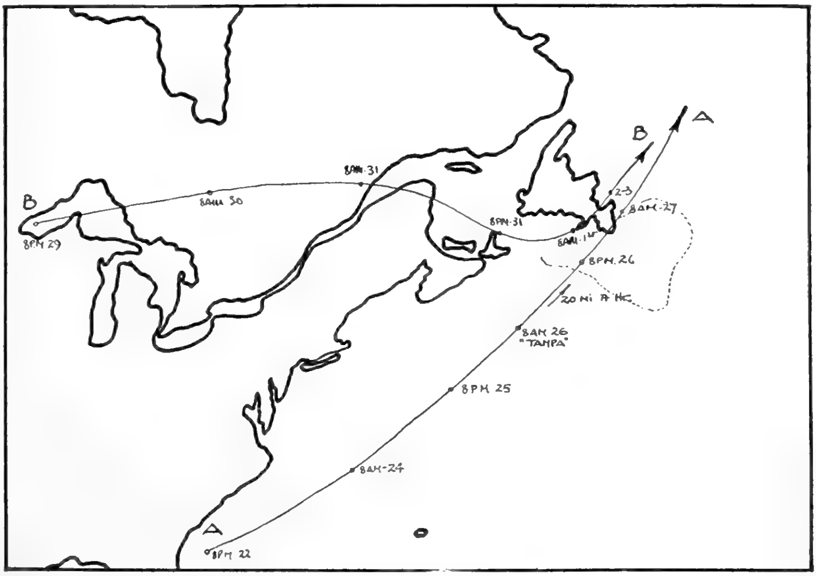

FIG. 2.—March cyclone tracks

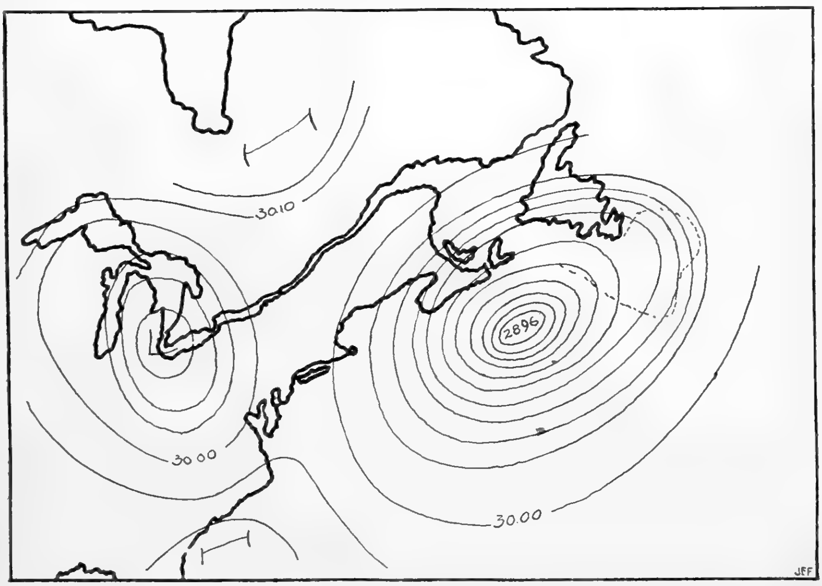

FIG. 3.—Isobaric map for 8 a. m. March 26, 1927. The center of the disturbance, traveling at the rate of 20 miles per hour, passed directly over the position of the "Tampa," then just south of Sable Island (see p. 33)

few hours, to the relatively cold Grand Banks regions. The weather for March, 1927, was much better than that for the same month in 1926. We experienced practically no fog and only 17 per cent hours

of low visibility in the nine days of March which we were at sea. There were four days out of the nine, however, during which the wind attained gale force.

APRIL

Disturbance C, Figure 5, was observed south of Chicago the evening of April 1, from thence it moved easterly, passing out to sea on the 3d instant. Several steamship reports from along the 40th

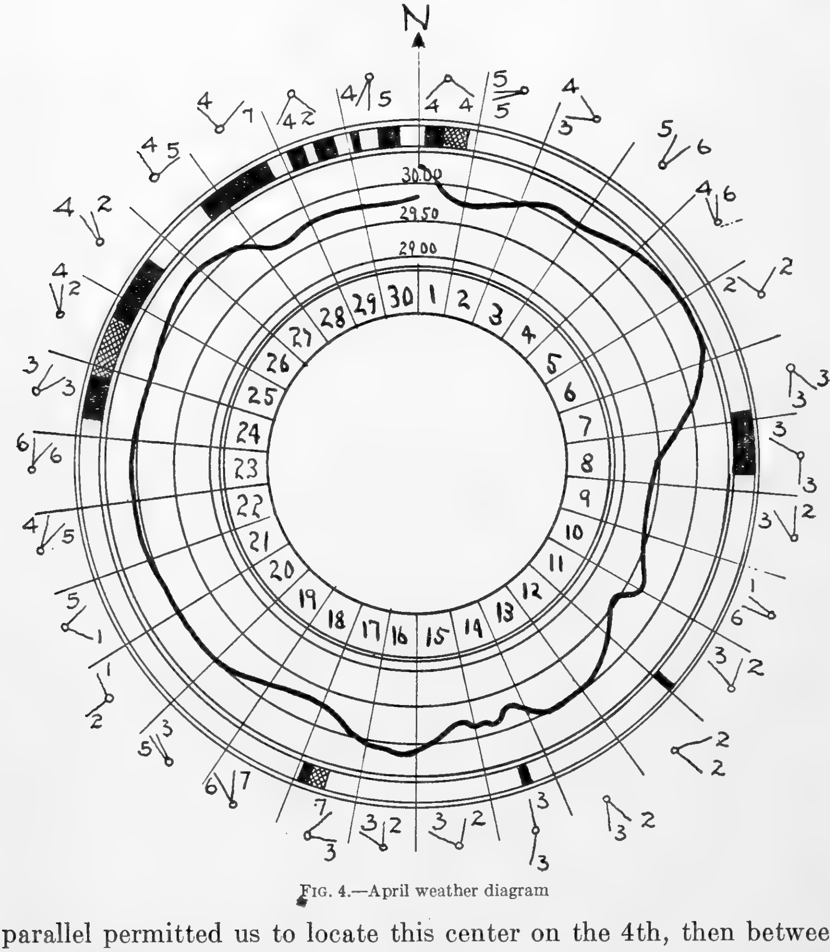

FIG. 4.—April weather diagram

parallel permitted us to locate this center on the 4th, then between our position and Bermuda. It was still moving in an easterly direction, and probably prevented from following the usual northeasterly course by a large anticyclone centered over the Gulf of St. Lawrence. The presence of this "high" moreover undoubtedly saved us from the discomforts of passing through another severe storm similar to the one experienced last month. The steamship *Majestic*, 200 miles southwest of our position on April 4, reported a very rough sea and a northeasterly gale. The path of this depression is shown as track C, Figure 5.

April 3 a new depression put in appearance over Iowa and during the next four days crossed the country, as shown on Figure 5, track D. An interesting feature in connection with this cyclone is that it brought to the Newfoundland region, an area of low pressure which prevailed there for the succeeding 10 days. In fact, the general distribution of atmospheric pressure over the eastern United States and out over the ocean including the ice regions, did not materially alter for the nine-day period, April 7 to 16. Such a stagnation in the characteristic progress of "highs" and "lows" is a rare phenomenon at this time of the year. The foregoing general conditions are shown on Figure 6. The patrol, cruising on the Grand Banks during this period, enjoyed excellent weather conditions.

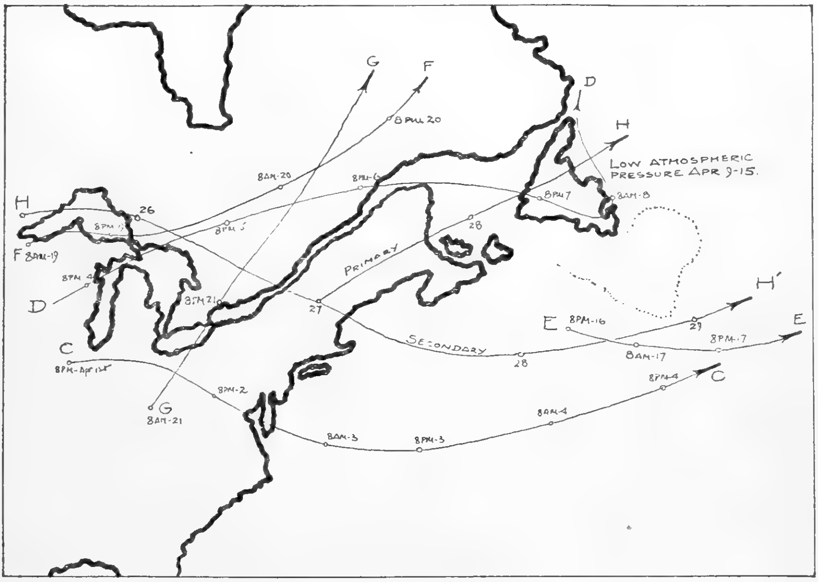

Fig. 5.—April cyclone tracks

An interesting meteorological phenomenon took place April 16, when in a locality about 150 miles southeast of Sable Island there was witnessed the development of a disturbance (cyclone) of restricted but considerable intensity. It traveled almost due east along the northern edge of the Gulf Stream and the forty-second parallel, and on April 17, passed about 140 miles south of the ice patrol ship. We experienced easterly winds of increasing strength early the morning of the 17th, which gradually backed to north and attained gale force by nightfall. The lowest barometer reading at this time was 29.70, clearly indicating that the *Modoc* was in the cold northern sector of the storm, the center apparently passing at the rate of 15 to 20 knots per hour. The strongest wind was from the north and north-northwest, and some snow fell during the night hours. Conditions indi-

cated that the depression was deepening and intensifying as it traveled eastward. The winds backed still further during the 18th and finally later in the day, gradually abated in force as the disturbance moved out into the North Atlantic and all influence had disappeared. Track E, Figure 5, is an excellent example of the birth of a cyclonic vortex in the atmosphere, probably materially aided by the presence of warm and cold masses of water along the southern border of the Nova Scotian continental shelf. This particular cyclone had its birth over the northern edge of the warm and cold water where the current curves up in the great oceanic bight west of the Grand Banks. Track E is an example of developments that may take place in the atmos-

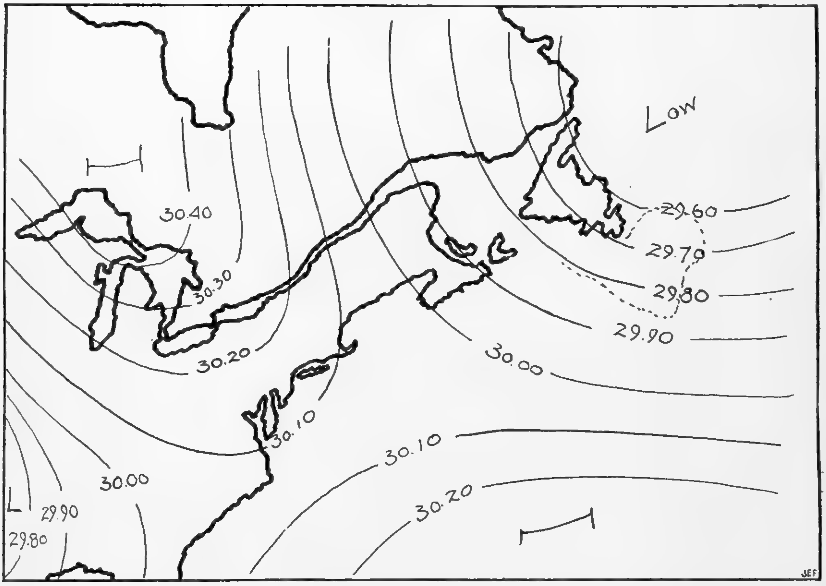

FIG. 6.—The general distribution of atmospheric pressure from April 7–16, during the nine days of which there was an unseasonable stagnation in the movement of "highs" and "lows"

phere over an ocean but where due to the scantiness of data, winds sometimes even of considerable intensity can not be explained by reference to the generalized weather map.

The distribution of pressure following the events described above took the form of a huge high pressure area extending from Newfoundland southward over the Atlantic States to Florida. This mass of air, however, gradually shrank in extent until on the 19th it centered over the Carolinas and by the 20th it had retreated completely to join the more or less prevailing "high" in the direction of Bermuda.

An expansive area of low pressure which had lain motionless since April 7 (for a period of about two weeks) over the Southwestern States, began to move about the 20th and simultaneously with the removal of the high pressure described in the preceding paragraph. Its track F, Figure 5, from April 18 to 20, is shown crossing northward to Lak

Superior and thence eastward, later curving to the left, and finally occluding in the direction of Labrador. Another depression moved from near Cincinnati, Ohio, where it had first formed, north-northeastward toward Labrador, and finally off the map.

It was noted this month that there appeared to be an excess of air over North America with the "highs" pushing the low-pressure centers to the northward and easily filling them up. The tendency for the atmospheric high pressure, especially over Nova Scotia and Newfoundland during April and the latter part of March, resulted in an abnormal percentage of northeasterly and easterly winds for the Grand Banks region. This condition was doubtless the underlying factor responsible for the notable westerly positions of the ice south of Newfoundland during April. A depression followed track G, on Figure 5, from 8 a. m. the 21st until 8 p. m. the 23d, when it disappeared from the meteorological map in the region of Labrador.

The next depression of consequence was centered just west of Lake Superior the morning of the 25th. It had advanced to Lake Huron by the morning of the 26th, and from thence it curved to the northeastward and finally on the 27th assumed an elongated shape covering an area from Quebec southward of Nantucket. (See track H, Fig. 5.) A small portion of this area apparently broke away from the main system and drifted southeastward and thence eastward, passing south of the Grand Banks on the 28th instant. We experienced fresh easterly winds in consequence and more fog than at any period this season. Newfoundland and the Grand Banks vicinity continued to have low atmospheric pressure for the remainder of the month.

Summing up, we are particularly impressed with the prevalence of easterly and northerly winds this year. This was due primarily to an excess of air which persisted over the Canadian Maritime Provinces and Newfoundland, where in normal season, low pressure usually prevails. This distribution of pressure and the consequent system of winds tended to hold the field ice and bergs nearer the continental slope than they normally would otherwise have drifted. There were, however, only two days, the 17th and 18th, upon which the wind attained gale force. Fog was present 16 per cent of the month and low visibility and fog 22 per cent.

MAY

The first week in May was characterized by a relatively large number, and frequency, of centers of low and high pressure. Families of cyclones, four and five in number, appeared on the meteorological map at time of observation instead of two or three as is normally the case, and as these several centers drifted across the ice regions the patrol experienced unsettled and changeable weather. The *Modoc*, returning to the patrol on the 9th instant, stated that similar weather condi-

tions were experienced in Halifax; first a warm day followed by one which was cool.

An unusually deep atmospheric depression was observed on the meteorological chart for the morning of May 9. The lowest barometer reading was recorded in Nebraska but the attending low-pressure system spread over a relatively large area of the central United States. This "low" moved eastward very slowly and assumed various shapes

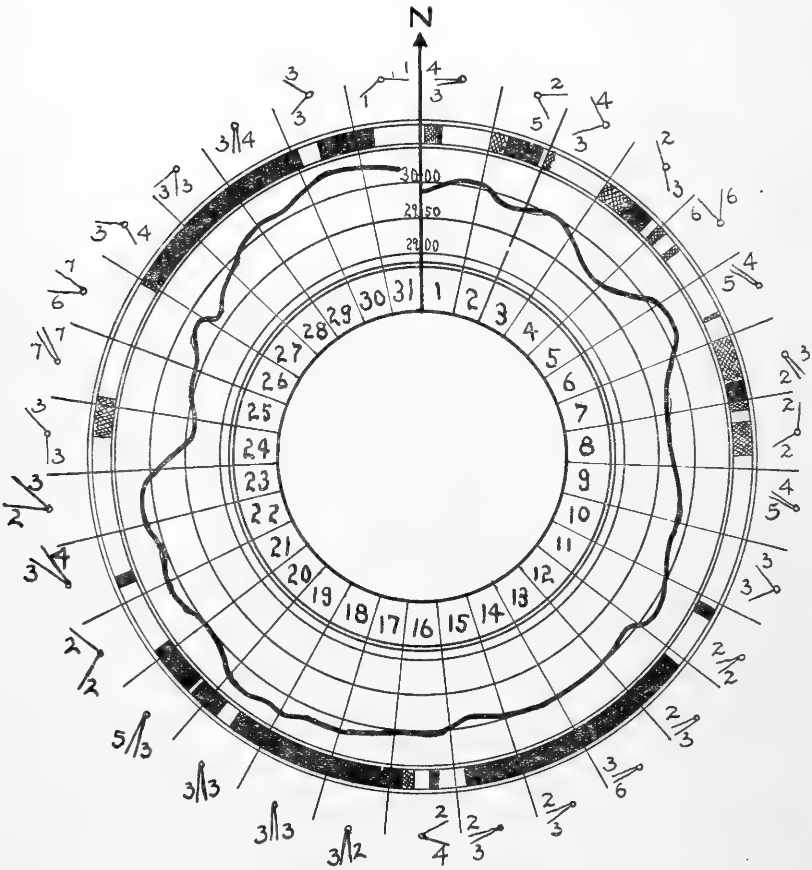

FIG. 7.—May weather diagram

and positions but remained at all times over the continent. The period May 11 to 20, consequently, was characterized by general low atmospheric pressure over the United States east of the Mississippi River Valley and extended eastward over the Maritime Provinces and Newfoundland. (Fig. 9.) These summer-time conditions brought southerly winds, rain, and a protracted spell of wet weather to the northeastern part of the country, and the ice regions coming again under prevailing southwesterly winds received the first prolonged period of fog for the season. We had almost continuous fog and low

visibility in the cold waters around the Grand Banks from May 11 to 20. (See Weather diagram, Fig. 7.)

FIG. 8.—May cyclone tracks

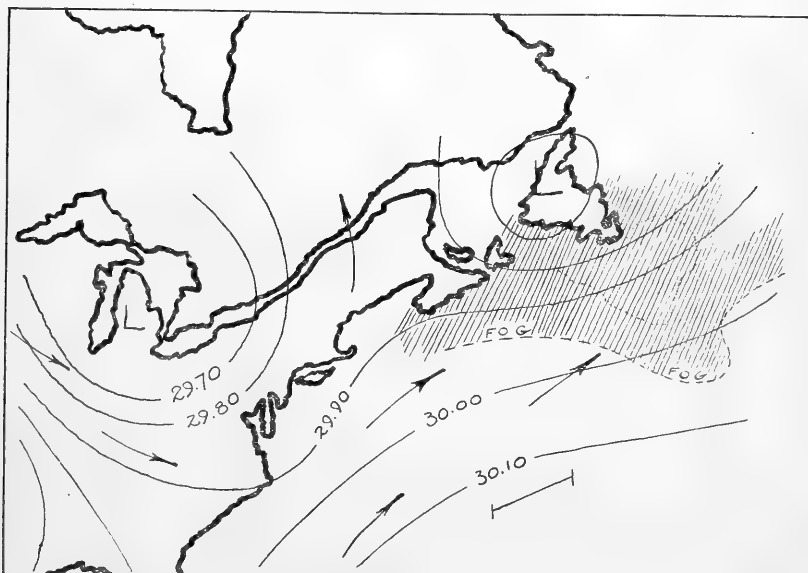

FIG. 9.—The distribution of atmospheric pressure May 11–17; a type of distribution that is common during the warmer months of the year. During this period of seven days the relatively cold waters of the Nova Scotian and Newfoundland Banks were enveloped in thick fog. The normal fog area under such conditions is shown as a shaded area on the figure

The meteorological map for 8 a. m., May 21 recorded the first material change in pressure conditiôns since the 11th instant. The pressure increased very rapidly over the eastern half of the United

States and a ridge in the atmosphere extended southward from Hudson Bay to Bermuda. New meteorological conditions came not as a surprise to the patrol as we had experienced stormy weather all day of the 20th which pointed toward a forthcoming change. Early the morning of the 21st, the fog rolled away before a gentle northwesterly breeze, revealing in all directions a hard, clear cut horizon. This was the patrol's first opportunity to scout for ice since May 9, 12 days previous. High pressure and clear weather prevailed from May 21 to May 27, upon the latter day of which fog and mist again shut in.

A disturbance of unusual intensity for this time of season marked the days of the 25th and 26th. The storm developed from a moderate depression over Montreal on the morning of May 22. The next day it moved eastward to the Gulf of St. Lawrence and deepened to a minimum of 29.66 recorded at Harrington, Quebec. It finally paused in its northeasterly progress because Cape Race and ships to the eastward on the 24th instant reported pressures of 29.35 and 29.29. The patrol ship, 150 miles to the southward, recorded a pressure of 29.50, but no stormy conditions existed and the winds continued light from the westward. Early the morning of the 25th, however, our barograph began to rise rapidly and the wind increased correspondingly in force from a northwesterly direction. At 8 a. m. it was blowing with gale force and a ship northeast of Cape Race, about 300 miles from the patrol, reported a barometer reading of 28.60. Situated on the rear of this disturbance we experienced one of the strongest gales and roughest seas for the season of 1927. Conditions slowly grew better on the 26th, and the wind shifted to light southeasterly airs with low visibility ensuing. That the stormy conditions of the past few days had not ceased was apparent by glancing at the meteorological map for 8 p. m. of the 26th where we found depicted another well-developed but less deep depression than that of the 25th. It became centered east of Newfoundland where it remained from the 24th until the 26th and then another equally well-developed depression arrived from the westward and remained in the vicinity of Newfoundland until the 29th. It was plain to see that for some cause the atmosphere from May 26 to 31 had become unseasonably agitated.

The outstanding feature for the month was the changeable weather during the first nine days, followed by two weeks stagnation of "highs" and "lows," providing for the Grand Banks almost continuous fog and summer-time directions of wind. The latter part of the month was featured by increased activity in the atmosphere as high and low pressure centers followed each other across the map. We experienced only two days upon which the wind blew with gale force and we experienced 43 per cent hours of fog and 55 per cent hours of fog and low visibility.

JUNE

On June 1 a low pressure centered near Nova Scotia elongated its shape to the eastward causing easterly winds to blow around the Grand Banks. As this depression moved northeastward the wind hauled to the southward, but the "low" hovered in the vicinity of Newfoundland until the 4th instant, when it was displaced by a large anticyclone. The fog caused by the southerly winds during the first

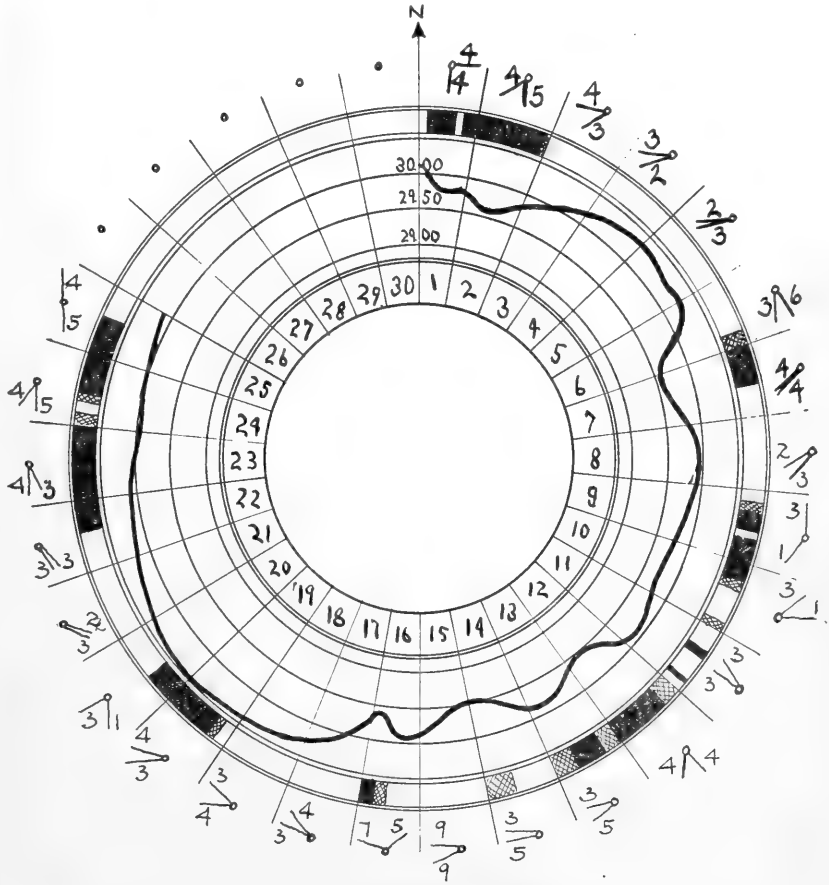

FIG. 10.—June weather diagram

three days in June lifted on the 4th, giving the patrol an opportunity to scout for ice during the succeeding four days. It was unusually clear June 7, when the anticyclone completely surrounded the Grand Banks, and on that day we sighted several bergs the exceptionally long distance of 20 miles away.

A disturbance was noticed on the meteorological map for June 3, it being centered over the Mississippi River Valley, and its path across the country and over the ice regions is shown on Figure 11, marked

"A." This "low" was of more than ordinary significance in that its passage was simultaneous with the stranding of a French fishing vessel on the southern coast of Newfoundland, 3 miles west of Cape Race. Its untimely appearance unfortunately caused strong southerly winds which quickly broke this vessel up on the rocky shore, thus making her a total loss. The passing of this storm brought the wind around to the westward and we again enjoyed clear visibility.

It was apparent from the examination of the file of daily meteorological maps that there was tendency for low pressure to spread over a large portion of the northern tier of the United States. In fact a depression stretched all the way across the northern part of the country with a "high" resting over the ocean in the region of Bermuda.

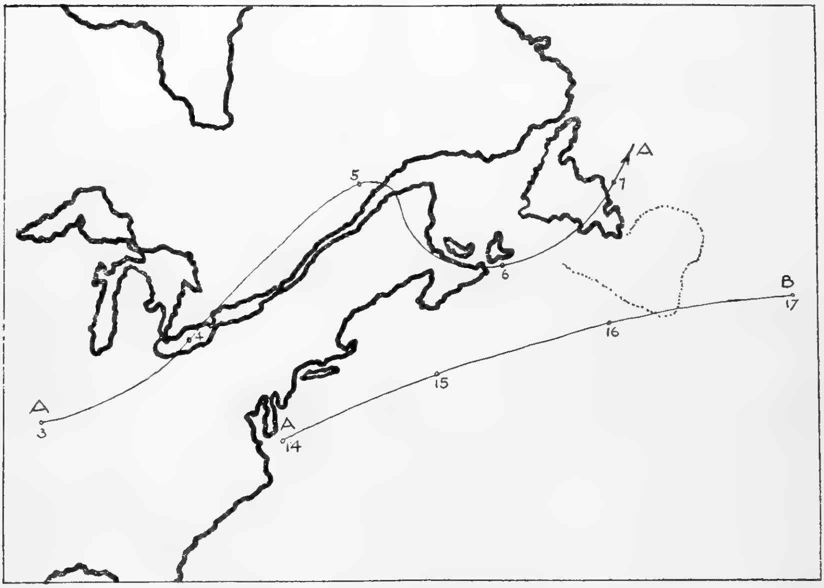

FIG. 11.—June cyclone tracks

Thus the stage was all set for the normal summer-time distribution of pressure, prevailing southerly winds, and much fogginess. Such conditions actually persisted from the 7th to the 14th instant, a situation similar to that which prevailed May 11 to 17 (see p. 41). On the 12th instant a high-pressure area was observed to be accumulating over the western plains and consequently we looked forward to a respite of clear weather.

The *Modoc* on June 13 was called eastward to the fortieth meridian, nearly mid-Atlantic, by a medical case and returning to the Grand Banks encountered a strong westerly gale. On the 14th the wind blew so forcibly that it was necessary to reduce speed to bare steerage-way. The great wind velocity was due to a disturbance northeast of Newfoundland, which deepened and intensified. No sooner had

the gale of the 14th abated than another disturbance was located about 250 miles south-southeast of Sable Island. It had been lost on the Weather Bureau's synoptic map, when it passed out to sea off the Virginia coast the 15th, but the ice patrol was able to plot its position quite accurately from a number of ship reports scattered over a large area. The winds accompanying this disturbance backed through the northeast, showing that the storm was passing to the southward of us and by the 17th the wind had weakened to a moderate breeze from the northwest, with fine weather again. The path of the cyclone is shown as track B on the weather map for the month. (See fig. 11.)

An anticyclone of expansive proportions followed closely in the rear of this disturbance, bringing northwesterly winds, high pressure and fine weather, the 18th, 19th, and 20th, but on the 21st, and 22d a general lowering of the barograph ushered in summer-time conditions, a shift of wind to the southern quadrant, and plenty of fog for the ice regions.

The first week of June was characterized by a large anticyclone and clear weather favorable for ice scouting. The second week low pressure over northeastern North America and high pressure in the region of Bermuda, gave southerly winds to the Grand Bank and much fog. The third and last week the patrol was in the ice regions we experienced two disturbances, one of which followed a track south of the Banks. There were two days during the month when the wind attained gale force. There was 33 per cent hours of fog and 43 per cent hours of fog and low visibility.

SUMMARY

The season's summary reveals the following facts: Probably the most outstanding meteorological event of March, at least for the patrol, was the passage of a severe storm center directly across the position of the *Tampa* southeast of Sable Island; the barometer recording a minimum of 28.96 inches. April 7 to 16 witnessed a general stagnation in the usual march of the "highs" and "lows," but the most important weather characteristic of April was the prevalence of anticyclonic conditions over Nova Scotia and Newfoundland, resulting in an abnormal percentage of easterly and northeasterly winds. May saw families of cyclones, and changeable weather up until the 8th, followed by a period of 11 days when a summer-time distribution of atmospheric pressure brought the first really long spell of fog. Gales and strong winds ushered out the month. June 7 to 14 there was a resumption of low pressure over North America and a return of the blanket of fog to the cold waters around the Grand Bank. The normal monthly percentages of fog based on 7 consecutive years of patrol records are: April, 24 per cent; May, 28 per cent; and June, 38 per cent. There was only one-half the usual amount of fog during

April this year; May, however, there was about double the normal amount, and June proved to be just about normal. A table showing monthly records of fog, fog and low visibility, gales, and calms for the 1927 ice season is shown below:

Month	Percentage (hours)		Gales (number of days)	Winds (average force)	Calms (number)[1]
	Fog	Low visibility			
April	16	22	3	3.6	0
May	43	55	2	3.3	0
June	33	43	2	3.7	0

[1] Based on 12-hour periods.

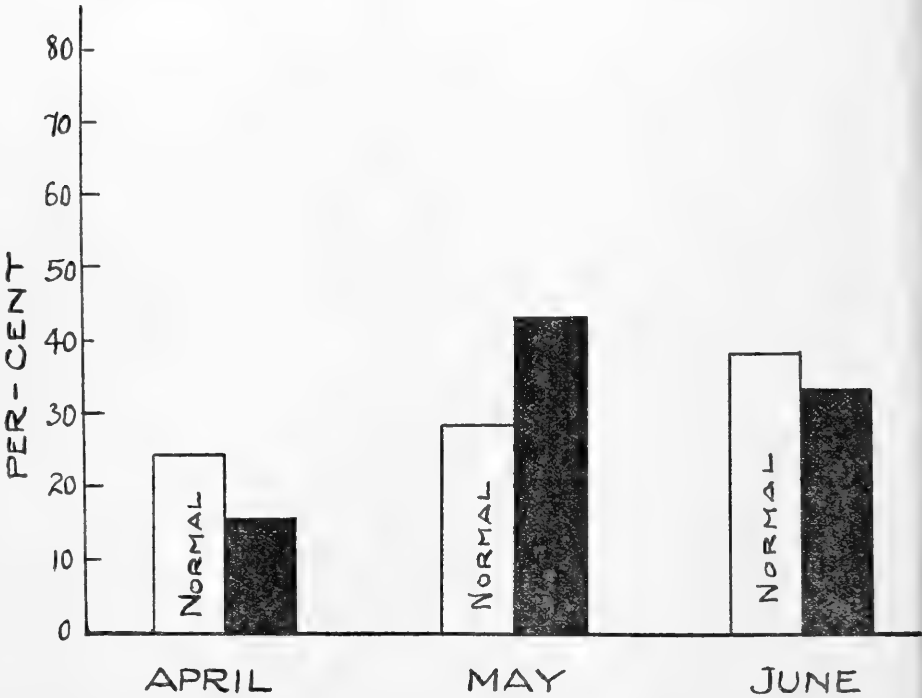

FIG. 12.—The monthly percentages of fog around the tail of the Grand Bank during the ice season of 1927, and as compared with normal

Figure 12 shows the monthly percentages of fog which was observed by the patrol around the Tail of the Grand Banks during the ice season of 1927. The percentage of fog that envelops the ice regions is always a subject of vital interest, since, obviously, fog and low visibility greatly magnify the danger of collision with icebergs.

COOPERATION WITH THE UNITED STATES WEATHER BUREAU

Following the procedure on previous patrols a meteorological map was constructed twice daily on board ship, the data being obtained from the general synoptic reports broadcasted by the United States

Weather Bureau from the naval radio station at Arlington at 10 a. m. and 10 p. m. Occasionally the weather experienced by the patrol vessel did not accord with the Weather Bureau's data when plotted on a base map. In such cases it was necessary to collect reports from as many ships as possible and well scattered within a radius of 500 miles of our position. This work often revealed the presence of disturbances that had formed or developed over the sea, the position of these storms being unknown to the Weather Bureau, at least when it had sent out its routine data.

Twice daily, as in former years, at 8 a. m. and 8 p. m., a report was dispatched to the United States Weather Bureau, Washington, D. C., and at the end of each cruise a more detailed report was forwarded by mail to the Washington weather officials.

ICE FORECASTING BY MEANS OF THE WEATHER

Last year's annual report (Bull. No. 15, pp. 45–48) contained an account of a scientific investigation carried on at Harvard University

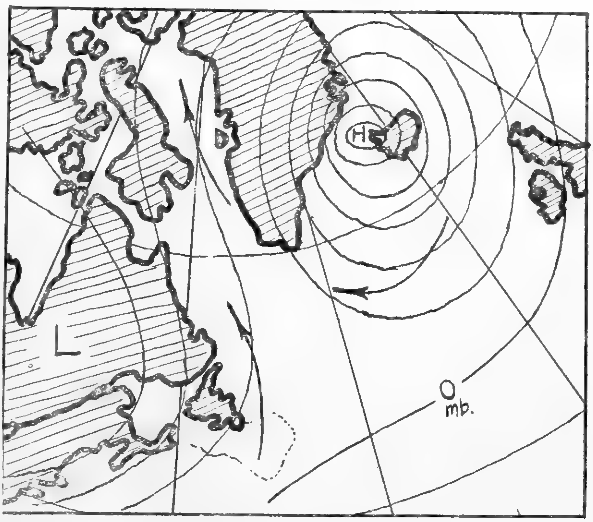

Fig. 13.—The anomaly of atmospheric pressure over the northwestern North Atlantic for the month of October, 1926. Isobars drawn every 2 millibars. Conditions when reflected the following spring spell less ice than normal

and later at the British Meteorological Office, London, into the possible relationship, between the varying amounts of Arctic ice from year to year and meteorological events occurring in the northern regions some months previously. It appears logical to believe that the prevailing direction of winds over the Labrador-Greenland region, when expressed in terms of departures from normal, and considered in monthly periods, would be reflected sometime later in the variations from normal in the amounts of ice. It has been found best throughout the investigation to work with differences from means, and this fact should be kept in mind by the reader.

The first factor, consisting of the atmospheric pressure differences between two points taken across the line of drift of the ice on its journey to the southward, is being furnished by the United States Weather

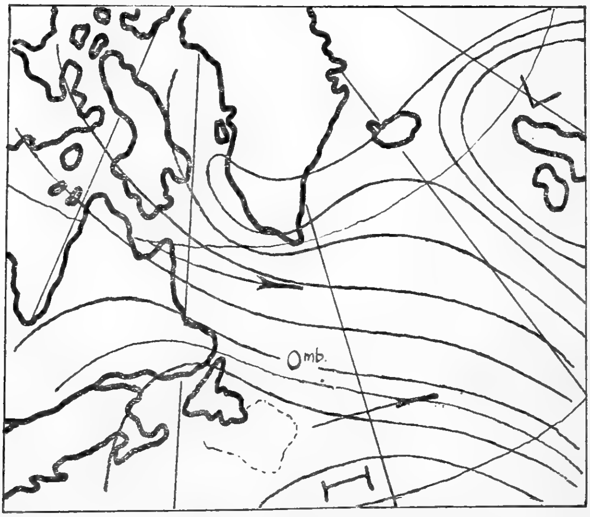

FIG. 14.—November, 1926, anomaly of atmospheric pressure. Conditions when reflected the following spring indicate more ice than normal

Bureau in the form of monthly mean pressure records from meteorological stations scattered around the shores of the North Atlantic. Observation points even in Greenland are now connected with the

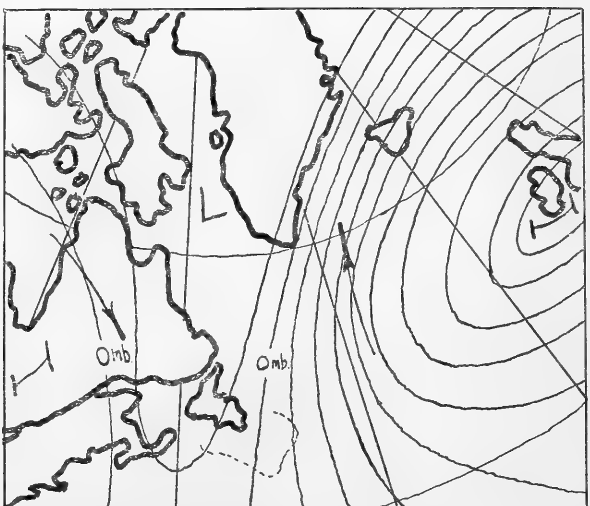

FIG. 15.—December, 1926, anomaly of atmospheric pressure. Conditions when reflected the following spring indicate a normal ice season

outside world by radio, a fact of great importance to the success of this particular ice forecasting problem. Maps showing the anomaly isobars, one map for each of the months, October, 1926, to March,

1927 (see figs. 13 to 18, inclusive), will give the reader a pretty fair picture of events leading up to the ice season of 1927. It is plain to

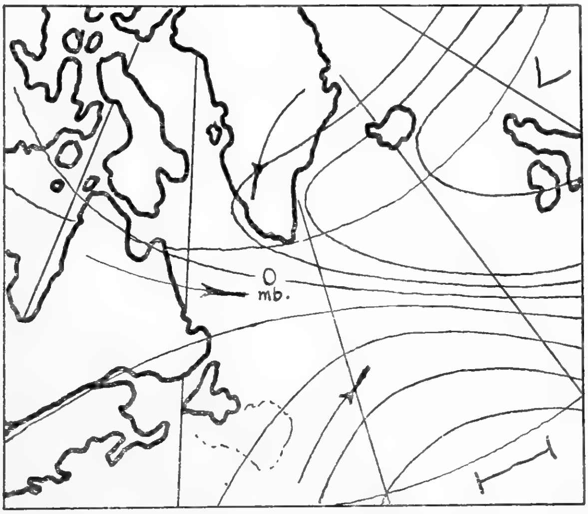

FIG. 16.—January, 1927, anomaly of atmospheric pressure. Conditions when reflected the following spring indicate more ice than normal

see, for example, that during October, 1926, meteorological conditions were less favorable than they usually are for Arctic ice to drift southward into the Atlantic. December, 1926, the winds were more

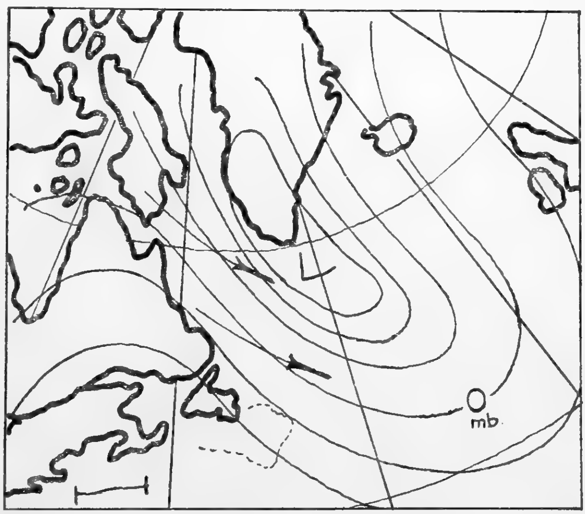

FIG. 17.—February, 1927, anomaly of atmospheric pressure. Conditions when reflected the following spring indicate more ice than normal

or less neutral, but November, January, February, and March were more favorable than ordinarily to a greater abundance of ice appearing in the spring of 1927 than is normal.

A more accurate method of measuring the value of the meteorological factor was found by our investigation to be an equation

$$\text{Bergs} = 4.8 - 0.08(c) - 0.12(d)$$

where the number of bergs is expressed as a value 0–10; c represents the pressure difference in millibars between Belle Isle and Ivigtut; d represents the pressure difference between Stykkisholm and Bergen. (For details of the values see Bull. No. 15, p. 48.)

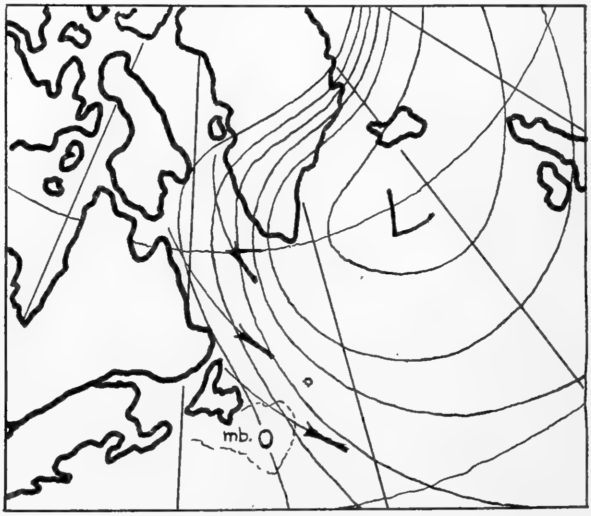

FIG. 18.—March, 1927, anomaly of atmospheric pressure. Conditions when reflected in the spring spell more ice than normal

A forecast was made in a letter, March 11, 1927, to the chairman of ice patrol board, that about 396 bergs would drift south of Newfoundland during 1927, or field ice and bergs somewhat in excess of that during a normal year. As a matter of fact we now know after a careful check that the number of bergs for the danger season, March to July, was 367, and about 390 for the entire year, and thus the forecast was quite accurate. (See iceberg table, p. 16.) The number of bergs may vary within wide limits; for example, in 1912 there were 1,200 and in 1924 only 11. The forecast in 1927 was purposely kept from publication because it is desired to test the work with a few more trials, but it all is most encouraging and the service will be continued for 1928.

DEPTH SURVEY CARRIED OUT WITH THE SONIC DEPTH FINDER

Work was continued during 1927 with that part of the scientific program which related to surveying the bottom contour in the ice regions whenever opportunity offered. The work really has two principal objects, (1) to contribute more cartographical information than is now on record of these little frequented regions, and (2) to learn more regarding the currents through a more detailed knowledge of the sea floor, because as we well know, the configuration of a sea basin casts an important influence upon the moving masses in it.

The sonic depth finder apparatus was operated this season by a member of the Coast Guard, a chief petty officer, who received an eight weeks' course of instruction at the Navy sound school, United States Navy submarine base, New London, Conn. The apparatus functioned quite satisfactorily throughout the entire patrol.

The calculations of the time interval used in multiplication to obtain the depth, were facilitated by a graphic means of division, the curves being constructed of a scale sufficiently large to permit interpolation to 2 in the third decimal place of the time factor. The velocity of sound in the water column, at the particular spot, was obtained by referring to the chart that was especially constructed for this region last year (Bull. No. 15, fig. 9, p. 49), in which corrections have been made for the influences arising because of pressure, salinity, and temperature. The geographical positions of the sounding were not accepted until they had been tested by several astronomical sights, and frequently supplemented by radio compass bearings from Cape Race.

There was a total of 435 soundings recorded this year which range from as shallow as 30 fathoms to as deep as 2,312 fathoms. A report and record of the data has been submitted to both the United States Hydrographic Office and the United States Coast and Geodetic Survey, in order that revision may be made in the proper charts.

One of the most important advantages that has been gained from the sonic apparatus by the patrol has been of a navigational nature. The distribution of the ice, and consequently the activities of the patrol, take place in general along the Atlantic faces of the Grand Bank, a region notorious for its fogs. In consequence the patrol vessels experience considerable difficulty in obtaining frequent and accurate astronomical "fixes." The depth of water, rapidly and easily taken by means of the sonic apparatus, however, quickly locates our distance in or out with respect to the bottom grade, while a radio bearing from the only station in the ice regions, Cape Race, fixes our position along the slope.

ICE OBSERVATION

It has been customary for a number of years to devote a section of the annual report to remarks on the behavior and distribution, in time and place, of all Arctic ice south of Newfoundland (the forty-eighth parallel of latitude). A certain amount of statistical work on this subject in addition to current reports, has been carried on by the ice patrol, especially that covering the amount of ice from year to year and from month to month. A complete report for those students interested in this aspect of the subject is contained in Ice Patrol Bulletin No. 15 (for 1926), pages 75 to 77. The ice observation for the season 1927 follows:

JANUARY

There was a total of four icebergs reported by steamers for the month of January. All of these bergs were distributed along a line

FIG. 19.—January ice map. The position of the first Arctic ice for the year 1927. △ represents an iceberg. There were four bergs south of the forty-eighth parallel during the month

between St. Johns, Newfoundland, and Flemish Cap. This information was obtained from Cape Race radio station by the ice patrol ship upon its initial arrival in the ice regions. Conditions were considered average, as a normal January records three bergs. (See Iceberg Tables pp. 75–76, Bull. No. 15.)

FEBRUARY

Field ice put in its first appearance on February 10, when reported in a position between Cape Race and Sable Island. This ice was doubtless of St. Lawrence origin, it having been blown offshore to the outer edge of the shelf. The first flat ice of Arctic origin was sighted on the 19th instant, from latitude 48° 20′ longitude 50° 00′ to latitude 47° 50′ longitude 50° 05′, the extreme northern part of the Bank, about 100 miles due east of St. Johns. There were seven other reports relating to the position of field ice during the month,

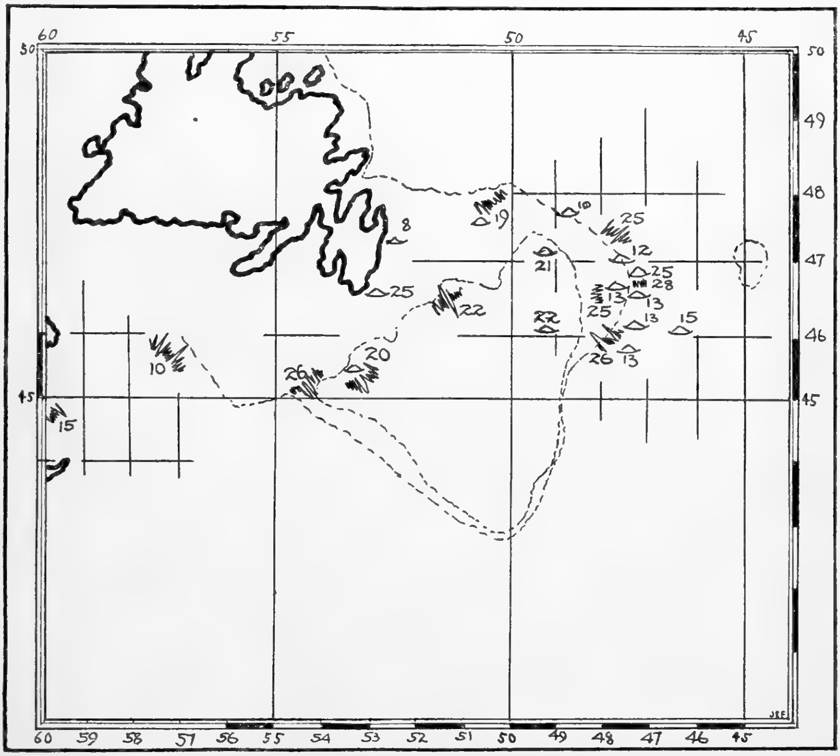

FIG. 20.—February ice map. \/\/\/\/ represents field ice. There was a total of 10 bergs south of the forty-eighth parallel during the month

the southernmost field being found in latitude 46° 00′, on the eastern slope of the Grand Banks. This southerly position indicated an invasion of nearly 120 miles, all which took place during the latter part of the month. A total of 10 separate and distinct bergs, it is estimated, drifted south of the forty-eighth parallel during February; the most of these moved south along the usual path parallel with the eastern slope of the Grand Bank. There were two exceptions when two bergs drifted toward Cape Race close in near the shore. The southernmost berg during February was reported on the 13th instant,

then just below the forty-sixth parallel between Flemish Cap and the Grand Banks. The normal number of bergs for February is 10, just what was observed.

MARCH

There was a total of 7 field-ice reports and 38 reports of icebergs received during the month, some of which, of course, referred to the same ice. No field ice, however, was sighted south of the forty-sixth parallel, a fact which showed the ice had not increased in abundance

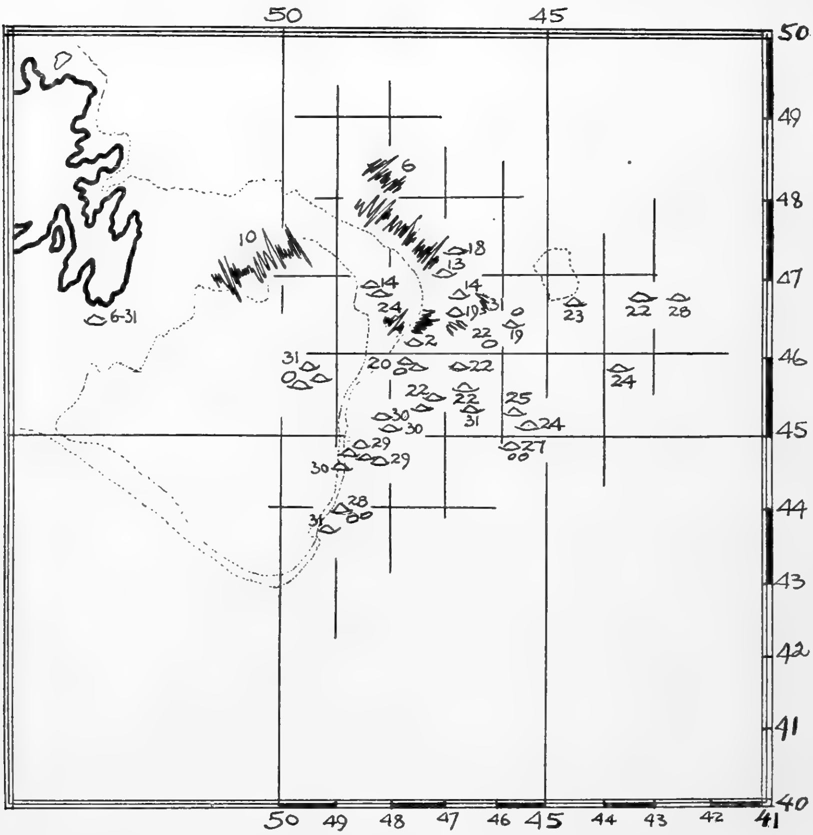

FIG. 21.—March ice map. There were 26 bergs south of the forty-eighth parallel during the month

sufficient to extend its boundary southward of a point observed in February. About half of the bergs drifted southeastward between Flemish Cap and the Grand Banks, and out on to the northern edge of the Atlantic water. The patrol sighted its first ice for the year on the 29th instant in the form of a small growler, latitude 44° 00′, longitude 49° 00′. The next day we made contact with the two southernmost bergs 44° 26′, 48° 40′. The patrol remained with the inshore berg (they being about 10 miles apart) for the last two days of March, during which time a drift of 1.4 knots per hour was recorded

to the southward, more or less parallel with the general trend of the Bank. It was noticed that the ice consisted of small bergs, which plainly showed the effects of last summer's disintegration in high latitudes; and, also, this is a characteristic form for the early season. An interesting incident was the case of a large berg which remained grounded about 7 miles southwest of Cape Race, in plain sight of the station, from the 6th day throughout the remainder of the month. It is estimated that there was a total of 26 bergs in the North Atlantic, south of Newfoundland, for the month. A normal March records 36 bergs south of the forty-eighth parallel and 4 south of the Tail, but this year none of the ice succeeded in drifting as far south as the Tail.

APRIL

The small berg which we had been standing by the last few days of March grounded on the 2nd instant in latitude 43° 31′, longitude 49° 28′, at a point where the contour of the Grand Bank projects abruptly out to the eastward. The drift covering March 29 to April 2 is shown on Figure 22. The neighboring berg, which on March 29 had been 10 miles farther offshore, drifted south faster in the current and was by this time no longer in sight, nor did we see it again in spite of a search covering the day of April 3. Its drift must have been offshore to the eastward as well as to the southward, where undoubtedly it was caught in the warm counter current. A small growler was reported on the afternoon of the 2d instant about 50 miles due south of the Tail. This was the southernmost position that ice had attained thus far this year, and we believe it to have been the same growler as one sighted by the patrol on March 30, 30 miles north of the Tail.

The patrol found a small berg and growler on the 4th about 35 miles almost due east of the Tail. We remained drifting near this ice the remainder of that day. It was moving southward at the rate of 1 to 1.5 knots per hour. A strong wind blew from the north during the night, and although we had been able to keep in sight of the growler, at daylight, the 5th, the berg was nowhere to be seen. Search was carried on for the entire day without success and we were forced to conclude that the berg had been set southeast, or east, into the warm offshore current. Since no ice was reported later to the southward, this behavior was somewhat substantiated.

Two small bergs were sighted April 7, the smaller in on the Bank and the larger about 10 miles east on the 100-fathom contour and about 25 miles north of the Tail. Fog shut in for the next two days, and when the patrol was next able to search, the larger of the two bergs was found southeast of the Tail, drifting in the heart of the current to the westward. We followed it as it swung to the northwest and later to the north, at about 0.9 knot per hour. Finally,

on the 13th, it entered water of practically no current in on the shoal of the Tail of the Bank itself. We remained near this berg until the morning of the 15th. It had calved several growlers, melted somewhat, and naturally was slowly becoming smaller. The water

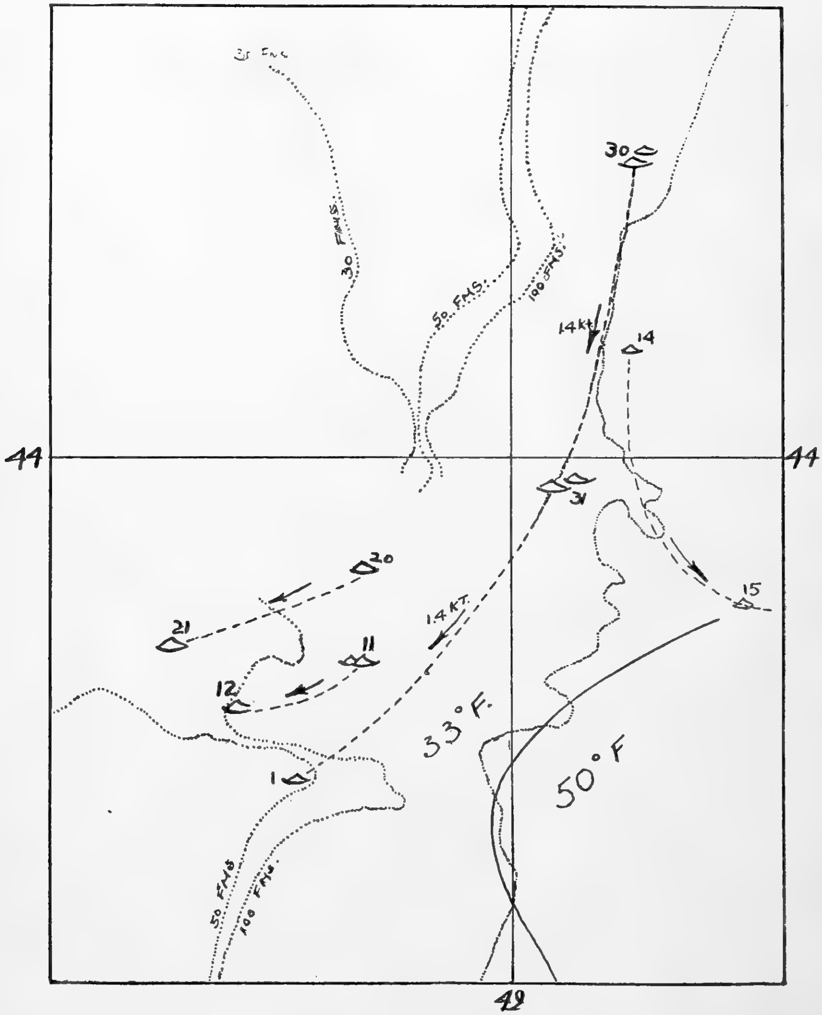

FIG. 22.—The drift of 3 bergs into the shallow water on the eastern side of the Grand Bank during April. Warm water from offshore pressing against the slope at this point is believed responsible for the deviation in the normal path of the ice

was relatively cool, 35° where it floated, and therefore not especially favorable for fast disintegration.

From the 10th to the 15th bergs were reported in positions scattered all along the slope from the Tail northward to the twenty-seventh parallel. A relatively great number of bergs, beginning with the 20th, were reported on the northern part of the Bank, as steamers began using tracks E bound for the Gulf of St. Lawrence.

The *Modoc*, on the 15th, searched around the Tail of the Bank to make sure no bergs had entered this area unobserved. April 16 the scouting was extended northward along the east side of the Bank and we sighted a large berg and growler near nightfall. The berg was surrounded by warm water, temperature 50° F., but inshore to the westward from its position we could plainly see the boundary line where the cold slope water began. The surface temperature for April 9 to 24 (fig. 54, p. 95) shows the relative positions of these two

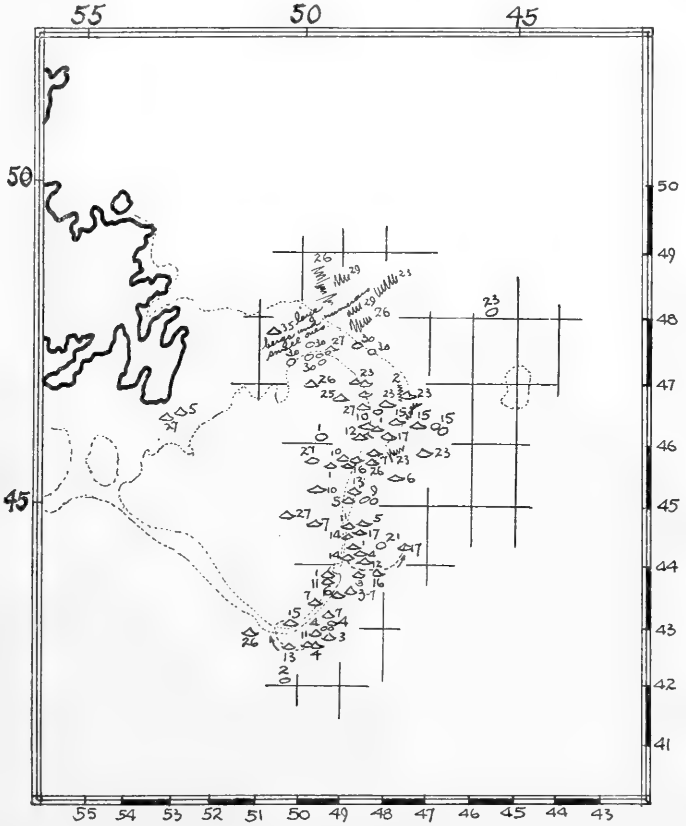

FIG. 23.—April ice map. There was a total of 93 bergs south of the forty-eighth parallel during the month

temperatured waters. During the next 24 hours this berg drifted a total of 17 miles and then a strong northerly gale broke it up rapidly into many growlers.

The 18th, 19th, and 20th were days of excellent visibility and the patrol ship took good advantage of the opportunity to search the eastern slope of the Grand Bank from the Tail to the forty-fifth parallel of latitude. Only three bergs were found in this zone; all of them had been carried by the cold current inshore on to the shelf, 15 to 40 miles inside of the edge of the Bank.

The fourth berg to drift south of the Tail was reported by a steamer on the 25th about 100 miles west of the Tail on the southwest slope. The patrol stood by it for the next three days when it had completely melted away. It did not drift during this period over 15 miles from the position first sighted. This ice was thought to be one and the same last seen by the patrol on April 21 then in on the Bank about 50 miles to the northward.

The last day of the month the steamer *Newfoundland*, on her regular run between St. Johns and Liverpool, reported passing a total of 35 large bergs and numerous small ones on the extreme northern edge of the Grand Bank. This suddenly boosted the number of bergs south of the forty-eighth parallel for the month above normal. The position of this ice was somewhat to the westward of its usual path along the eastern slope of the Bank and therefore we expected that most of the bergs would eventually drift to southwestward, toward Cape Race.

Field ice was reported twenty times and on one day, April 7, it stretched in a broken line with few interruptions from near Cape Race to the east edge of the Bank in latitude 46° 00′. The farthest south position was recorded on the 13th instant when an open field was sighted in latitude 45° 14′ on the eastern side of the Bank. A field also projected out of the Gulf of St. Lawrence, its southern limits being reported 25 miles north of Sable Island on April 19.

One of the most striking points in connection with the ice distribution for the month of April is plainly to be discerned by glancing at the ice map for the period. (Fig. 23, p. 57.) Practically all the ice sighted and reported for the month was confined to the limits of the continental shelf. This was due to the prevalence of high atmospheric pressure over Canada and Newfoundland giving a consequent predominance of northeasterly winds combined with the oceanic fact that warm Atlantic water pressed closer to the continental slopes during April than is normal for the season. These two factors also interfered with the normal southward distribution of the Arctic ice.

There was a total of 189 ice reports relating to the positions of 93 bergs during the month of April south of Newfoundland (the forty-eighth parallel). Only 4 bergs, however, drifted south of the Tail of the Bank. A normal month provides for 83 bergs south of the forty-eighth parallel and 9 south of the Tail, therefore icebergs during April were slightly in excess of normal, but the southward distribution was not.

MAY

The 1st to the 5th days of May provided on the whole a very good visibility, affording the patrol an opportunity to search northward along the eastern slope of the Grand Bank. No ice was seen or reported, however, during this interval south of the forty-seventh

parallel. On the 6th and 7th days of May the *Tampa* sighted approximately 100 bergs, most of which were found in an area bounded by parallels 47° 50″ and 47° 30″ and meridians 50° 30″ and 51°, an area of about 36,000 square miles situated about 150 miles northeast of Cape Race. This great quantity of ice apparently was drifting southward eventually to ground on the northern part of the Bank; many of the bergs it was expected would succeed in drifting toward Cape Race while a much less number would probably follow the 50 and 100 fathom contours down the east side of the Bank. The fact that over 100 icebergs were in these regions on the northern slope of the Bank was considered an event of especial importance, particularly in view of the fact that the Cape Race tracks, leading directly through this area, would become effective May 15 and thus endanger those steamers bound to and from St. Lawrence ports. May 7 to 11 was spent near the southernmost known berg on the east side of the Bank near the forty-sixth parallel in 40 fathoms of water. The berg apparently was aground, or else there was no current at that place, because it did not change its position materially for four days. The patrol during this time broadcasted warnings every six hours regarding the unusual quantity of ice then present on the northern part of the Bank.

May 11 to 16, the fog settled over the cold, ice-infested waters on the northern part of the Bank, cutting off all opportunity to observe the behavior and drift of the bergs. It was with surprise that we received a report of a growler on May 15, in latitude 41° 57′, longitude 49° 53′, but the steamer which made the report added her inability to secure "sights" for the past two days and this naturally made the position very uncertain. In view of subsequent events, the presence of ice in this locality, approximately 60 miles south of the Tail, is deemed very unlikely. The patrol ship during the foggy spell, 11th to 16th, employed its time almost exclusively in making a survey of the circulation along the eastern slope of the Grand Bank and southward around the Tail (see p. 80).

May 21 was the first clear day for a fortnight and so we searched northward along the east side of the bank, and as guided by the boundary between the two currents, which now it had been possible to delineate on the current map just compiled. A considerable amount of ice was reported on the 21st instant. For example, the steamship *Calgaric* sighted about 38 bergs on the Cape Race tracks between longitude 49° 40′ and 50° 30′. These were thought to be part of the same large group last seen by the ice patrol on May 6.

May 23 to 27 were days of clear visibility and accordingly the patrol ship searched northward from the forty-fifth parallel all the way to the twenty-seventh parallel. A total of six bergs were sighted, which comprised the southernmost group on the eastern side of the Bank. The farthest south berg on the 23d instant was

recorded in latitude 46° 19′, longitude 47° 56′. The fact that there were so many bergs east of Newfoundland on the Grand Banks and that there were none south of the forty-fifth parallel was a truly remarkable condition. We made a report on this subject to the commander of the ice patrol on May 23, and, as it well describes the foregoing situation, it is included herewith:

I would like at this time particularly to invite your attention to the important events that have featured the ice patrol of 1927 and, as guided by the present conditions, to outline the probable general character and ice behavior for the remainder of the season.

As a result of research work abroad and at Harvard University carried out by the ice patrol, a prediction was made in March that approximately 396 bergs would drift south of Newfoundland in 1927. The termination of the field-ice season (usually the first half of May) now permits us to make a more accurate statement regarding the number of icebergs. The final forecast is close to 360 bergs, or a year quite similar to 1926, and one that is normal in number. To date there has been recorded a total of 224 icebergs south of Newfoundland, so that about two-thirds of the forecasted number have already put in an appearance. Both the ice and its time in season, therefore, are running along in harmony so far with predictions.

The first third of the season of 1927 was characterized by an unusual predominance of northeasterly winds, and this fact, combined with the presence of great masses of warm Atlantic water close in to the Grand Banks' slopes, interfered very markedly with the normal southward distribution of the icebergs. These facts were made the subject of a dispatch to headquarters on May 4 last. It is remarkable that nearly all the bergs this year have been confined to the northern part of the Banks and the coastal shelf, and only five bergs have drifted south of the Tail. None of these, moreover, have at any time endangered the United States-Europe steamship tracks.

The second third of the ice season, in which we are now well advanced, is distinguished for the cessation of the Labrador current southward around the Tail of the Bank, where normally it flows at 0.5 knot per hour at this time of year. A current survey covering about 40,000 square miles of area, equal to the size of the State of Pennsylvania, was carried out by the *Modoc* May 10–21, and the results of this work are shown on the current map of water around Grand Banks, May 11–21, 1927. The direction and velocity of the circulation have been calculated in accordance with methods contained in Coast Guard Bulletin No. 14 and includes the resultant movement of the mass in which an iceberg would normally float. It can be seen from the above current map that the warm offshore current presses unusually far inshore against the continental slopes. The current runs northward even, on the east side of the Bank in latitude 43° 50′, right in to the 100-fathom depth. Thus the warm current has tended to dam the icy current from the north (the Labrador) and has caused its main branch to be deflected south of Flemish Cap. The original of this chart is at present of invaluable assistance in guiding the patrol ship in its scouting work for icebergs.

Naturally a subject of special interest at this time is to learn, if possible, the behavior of the ice and the course of events during the last third of the season. Considering the present ice situation, viz, about 70 bergs and growlers on the northern part of the Grand Banks, plus 100 more bergs expected, and the position of the two ocean currents, leads to the belief that few, if any, bergs will succeed in drifting south of the Tail of the Grand Banks. In other words, present conditions indicate that the ice menace for the United States-Europe tracks will

continue to dwindle throughout the remainder of May and June. The Cape Race steamship tracks (used by St. Lawrence ships), however, where they cross the continental shelf, may expect to be hampered with about 100 more bergs and probably lasting well into August.

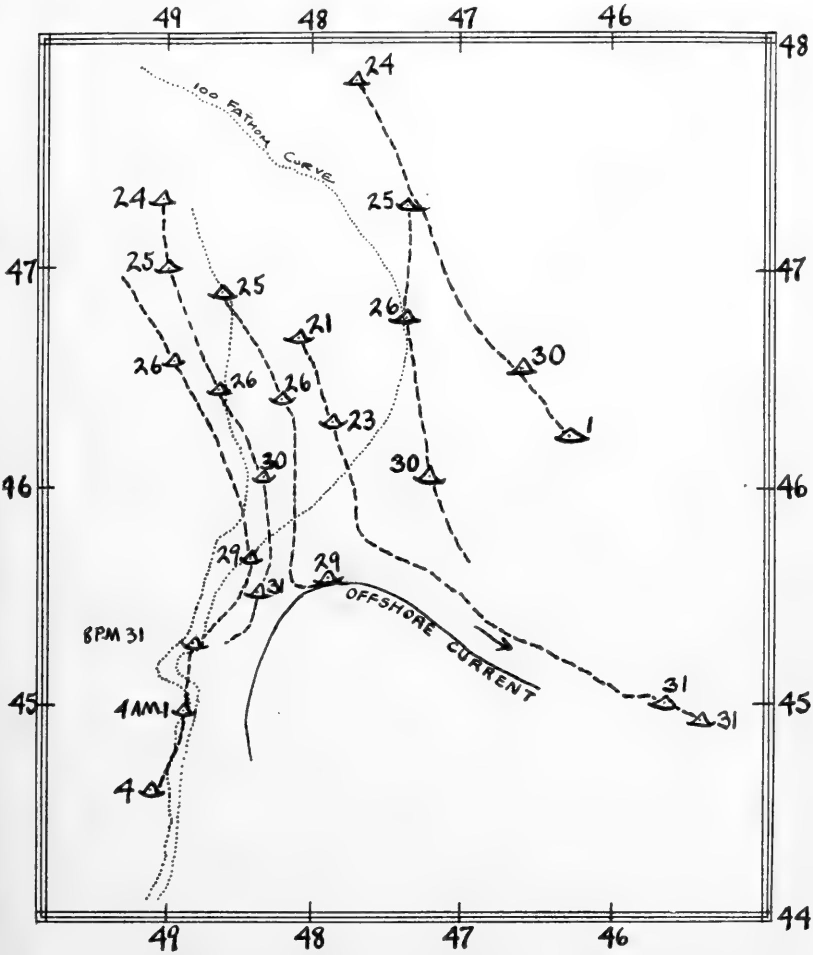

FIG. 24.—The northeastern Grand Bank promontory showing the drift of a number of bergs observed by the patrol May 24–31. The drifts were temporarily accelerated by a northerly gale which blew on the 25th and 26th instants

The summary is as follows:

First third of season:

(*a*) Normal number of bergs but held up in northern waters.

Second third of season:

(*b*) Inshore invasion of warm northeasterly countercurrent to the ice.

Last third of season:

Probable accentuation of (*a*) and (*b*).

A northwesterly gale blew on the 25th and 26th of May and its influence tended to accelerate the southward drift of bergs then on

the northeastern side of the Bank. Drifts averaging 1.2 knots per hour (30 miles per day) were observed and are shown herewith in Figure 24.

The southernmost iceberg, reported elsewhere on May 23, eluded our search on the 26th after the gale had subsided. The next day the wind changed to the south quadrant and low visibility and fog postponed further scouting operations. A berg was reported twice on the last day of the month in latitude 44° 53′, longitude 45° 38′,

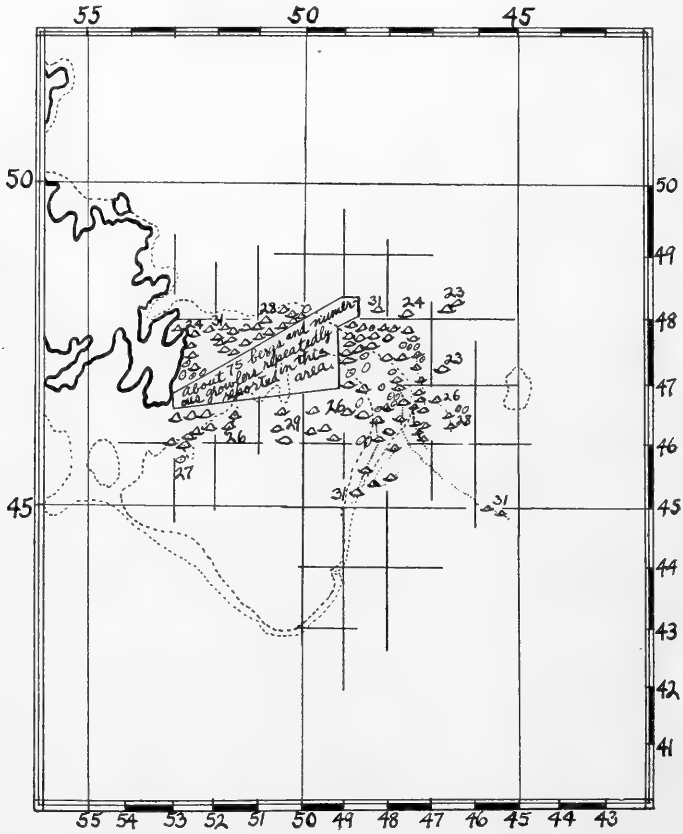

FIG. 25.—May ice map. There was a total of 153 bergs south of forty-eighth parallel during the month

and such a drift to the eastward from the position of the berg last seen on the 23d would indicate that this was one and the same berg.

The patrol ship sighted a total of five bergs on the 26th of May, strung out along the northeastern contour of the Bank and drifting southward more or less parallel to the general trend of the slope. Foggy weather again intervened on the 27th, 29th, and 30th, and, not being able to search for ice, we ran two lines of oceanographic stations normal to the slope just north of the forth-sixth parallel. On the 31st it cleared again and the patrol searched to the westward near

the slope in this same vicinity and two bergs were found fairly close inshore near the 100-fathom contour. It was believed that these two bergs were part of a group of six last seen on the 26th instant, and Figure 24 shows quite clearly their direction and rate of movement. The fact that they were observed to be drifting southward at 1.2 knots per hour agrees, moreover, almost exactly with the calculated rate determined by the density observations. We drifted near the inshore and southernmost berg the night of the 31st at the rate of 1 knot per hour to the southward, and thus ended the month.

Summarizing for May, we estimate a total of 153 bergs were south of Newfoundland (forty-eighth parallel), or 23 more than for a normal year. The most striking feature with reference to the distribution of the bergs was the complete absence of any ice during the entire month around the Tail of the Bank where the presence of 18 bergs is normal. The southernmost berg for the month, if we disregard the report on May 15, which was considered erroneous, was the berg observed on the 31st instant in latitude 45° 04′, longitude 49° 54′ or, no in other words, no berg was sighted within 200 miles of the United States-Europe steamship lanes during the month of May. This all tended, of course, to concentrate the ice on the northern part of the Banks where it gravely endangered steamships bound to and from St. Lawrence ports following the Cape Race tracks.

JUNE

The first two days in June were foggy, but in spite of this fact we sighted a small berg on the northeastern slope of the Bank. The next two days we spent on the current survey, but on the 4th instant we again sighted the berg last seen on the 1st. It had drifted south very little during the interval of three days and now was just south of the forty-fifth parallel. As the berg was apparently in the dead water on the Bank and consequently showed slight indications of drifting far from this spot, we left it again scouting northward for ice, and during the next three days searched the continental slope all the way to the forth-seventh parallel and westward to Cape Race. June 5, a Sunday, we sighted four bergs on the slope on the northeastern edge of the Bank and the next day located a total of 30 bergs distributed along the northern slope, the greatest number being found near latitude 47° 50′. This area has been inclosed on Figure 26 and labeled accordingly.

The *Modoc* assumed patrol duty on the 8th instant and immediately stood eastward, intending at first to search between the forty-seventh and forty-eighth parallels, just north of the area which the *Tampa* had recently covered. Fog and low visibility, however, modified these plans to a considerable extent, and so we were obliged to steer a straight course offshore to the edge of the slope. A few bergs,

nevertheless, were sighted along the 47° 30′ parallel, the work being further assisted by the steamship *Arabic* which passed during the afternoon of June 9 about 5 miles north of us. It was estimated that to date there were a total of 65 bergs present for the month south of Newfoundland (forty-eighth parallel), but nearly all of the ice was north of the forty-sixth parallel and distributed in various positions

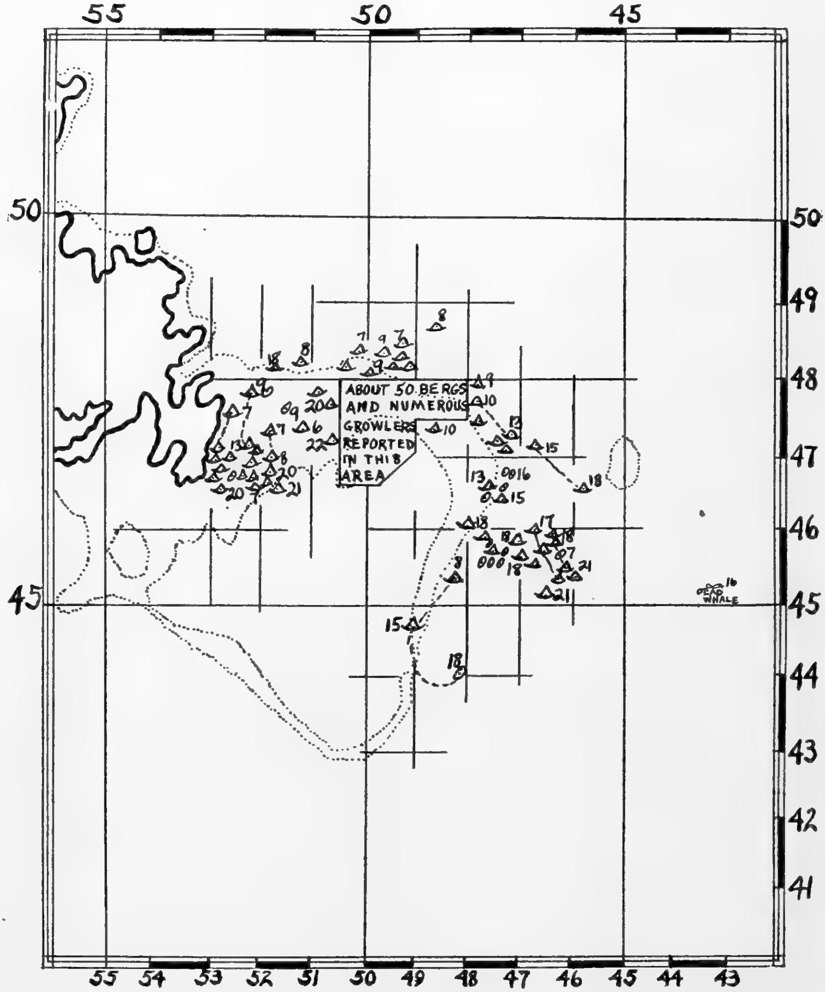

FIG. 26.—June ice map. There were approximately 95 bergs south of the forty-eighth parallel during the month

along the northern slopes of the Grand Banks. It appeared to exhibit no appreciable drift; if anything, it was working slowly to the southward farther in toward shallow water and, of course, break-up at a seasonal rate. Those bergs which were on the extreme northeastern side of the Bank, however, were being carried to the southward in a path more or less following the trend of the slope.

The direction and velocity of the circulation are clearly shown in considerable detail on the current map for the period, Figure 50, page 90.

The southernmost ice was the small berg previously mentioned in the first part of our remarks, just south of the forty-fifth parallel on the east side of the Bank. It was reported again and for the last time on the 8th instant, reduced now to the size of the growler in latitude 43° 54′, longitude 48° 22′. It evidently had drifted off the slope and been caught in the warm countercurrent which pressed into the westward at this particular point. (See the ice map for June, fig. 26.) Only four bergs succeeded in drifting south of the forty-sixth parallel prior to the 8th instant and all but one of these was deflected off to the eastward, south of Flemish Cap.

On June 10, when just north of the forty-seventh parallel and bound off the slope on a line of oceanographic stations, we sighted 12 icebergs scattered between the 50-fathom and 100-fathom curves. The southerly current in this zone was calculated to be 0.3 to 0.2 knot per hour. (See fig. 50.) Two of the same bergs were sighted again on the 11th, they having drifted southward to the forty-seventh parallel and followed the general trend of the slope, a drift which accords very closely with the current as calculated and drawn on the current map. (See fig. 50, p. 90.)

We were absent from the patrol grounds from the 13th to the 17th instant, but upon our return at the latter date a total of five bergs and several small pieces of ice were sighted in the vicinity of latitude 46° 00′, longitude 47° 00′, as shown on the ice map for the month. (Fig. 26.) This was believed to be the same ice as that last seen by the patrol on the 9th and 10th, then on the northern part of the bank. These bergs were reported again by a steamer on the 21st near the forty-fifth parallel and somewhat to the eastward, following a path in general conformity to the stream lines of the current. Few bergs were sighted on the northern tracks during this period, despite the fact that it was clear weather in that locality. We kept a careful record of the ships on the Cape Race tracks for a period of four days and estimated there were a total of 15 bergs the latter part of the month in this region. This would indicate that three-fourths of the number sighted up to June 9, or 50 bergs, had melted during the interim of two weeks, a sum which appears rather high. Probably some of the missing number might be found upon further search southward in the shoal water of the Bank, a locality which is seldom crossed by passing vessels.

We estimate there were a total of 95 bergs south of Newfoundland during the month, or 27 more than the average. The bergs remained concentrated on the northern part of the Banks, a condition which was also noted during May. Only one berg drifted south of the

forty-fifth parallel, and that one only to latitude 43° 54′, longitude 48° 20′, on the east side of the Bank, where it melted. When we left the ice regions, June 25, there were approximately 20 bergs on the northern slopes of the Grand Bank and 3 bergs near the forty-fifth parallel drifting to the eastward on the northern edge of the Gulf Stream.

SUMMARY

We now come to the summary of the season of 1927, the spring and early summer of which were characterized by a number of bergs

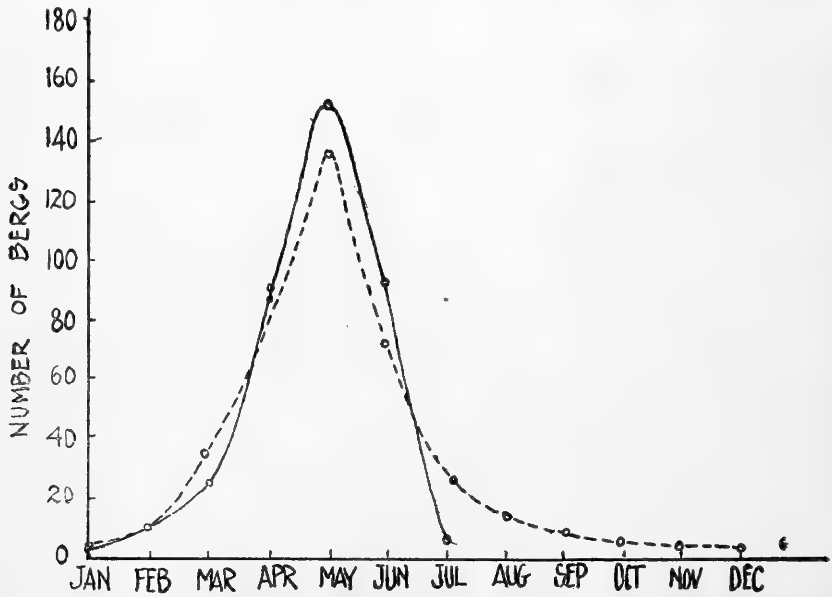

FIG. 27.—The distribution of icebergs south of Newfoundland, by months, during 1927. The full black line represents the actual observed numbers, while the dotted line represents the number which drifts south in a normal year

slightly in excess of normal. The distribution by months was as follows:

January	4	April	93	July	5	October	0
February	10	May	153	August	3	November	0
March	26	June	95	September	0	December	0

The foregoing table is shown graphically by Figure 27 appended herewith. The most striking fact in connection with the behavior of the icebergs in the North Atlantic during the spring of 1927 was their incomplete normal southward distribution. The bergs not being disposed as they usually are, consequently became concentrated from May 10 to June 15 in great numbers on the northern part of the Grand Bank where they constituted a distinct menace to steamships plying the Cape Race tracks. The uneven geographical distribution was attributed to the predominance of easterly and northeasterly winds during March and April combined with the inshore invasion of the warm Atlantic countercurrent.

The fact that only two bergs drifted as far south as the Tail of the Bank places the season of 1927 comparable with those in 1924 and 1925, two years noted for the absence of ice near the regular steamship tracks. The United States-Europe steamship lane routes during 1927, in fact, were at no time endangered on this score, and the conditions can best be presented by referring to Figure 28, which shows that during April there was only one berg that drifted as far south as the Tail of the Grand Bank, it being on April 13, its southernmost point, 90 miles to the north. During May the closest an iceberg approached the steamship lanes was on the 31st instant, when it was 210 miles away. June 8, the nearest that any berg drifted

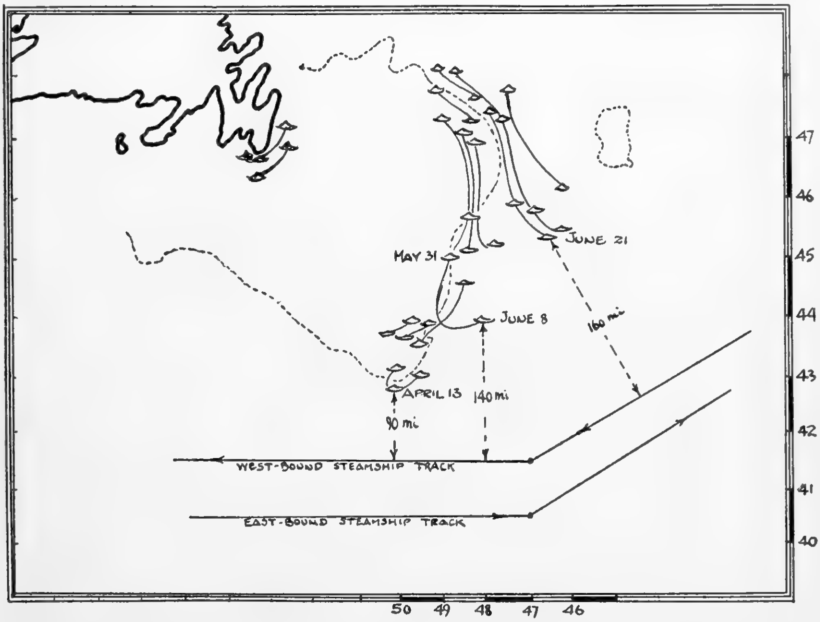

FIG. 28.—The nearest positions which bergs attained to the United States-Europe steamship tracks during 1927. Also, there is shown all the bergs that the ice patrol was able to follow in their drift

during the month, was 140 miles to the northwest of the United States-Europe lanes.

As in former years, the ice patrol kept track and recorded the drift of as many bergs as possible during the season, and the paths followed are shown on Figure 28. A record of all the icebergs that the patrol has been able to chart and follow since 1914 is shown as Figure 29.

As a result of the observations concerning the courses which bergs have followed near the southern end of their transport, we are including this year a map (fig. 30, p. 69) which shows diagrammatically the general berg paths and the most likely offshoots. Icebergs approaching the northern slope of the Grand Bank take any one of three paths a, b,

or c, depending upon the oceanographic and meteorologic conditions and the position of the ice geographically. Path c has six most probable points of departure. A berg embarking on path c may follow any one of the branched arrows e, f, g, h, and i. In early season—that is, in February and March—bergs characteristically

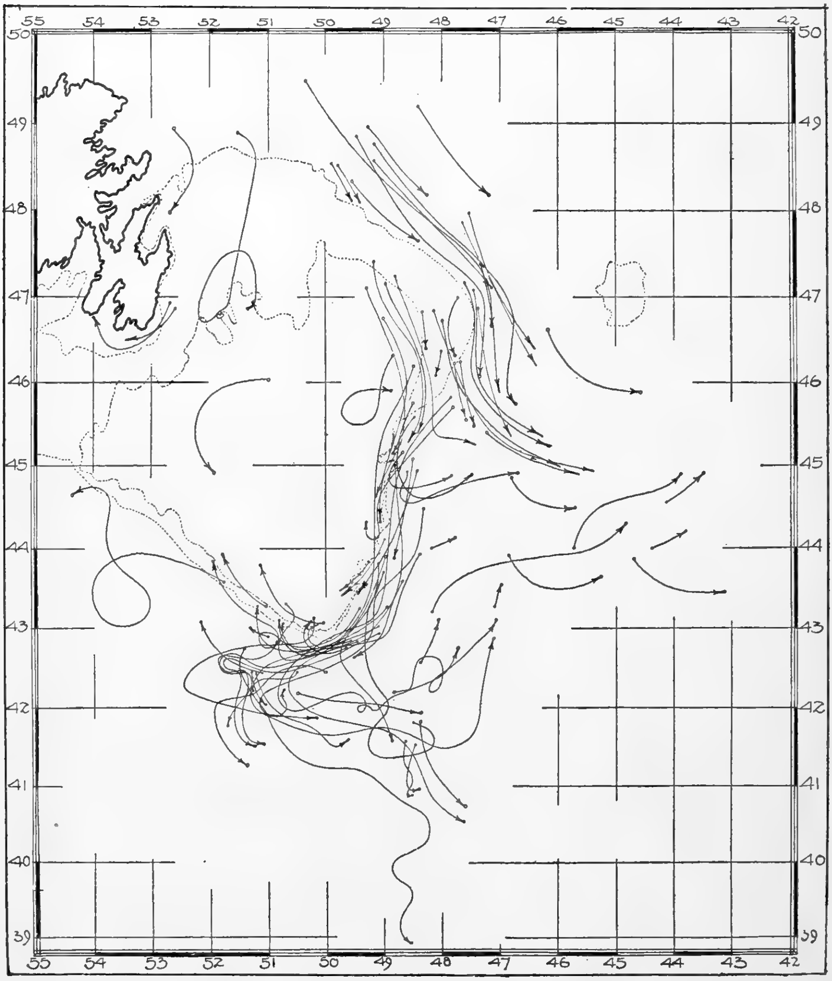

FIG. 29.—The drift tracks that bergs have followed since 1914 around the Grand Bank, as compiled from all records of the international ice patrol

follow branch d, but later in April, May, and June the ice follows any of the other branches farther to the south. Path i is, of course, the most dangerous for the steamships, as the ice there slowly crosses the United States-Europe steamship routes. Branch i, moreover, invariably lies between meridians 49 and 47, but fortunately it is a very small percentage of the total number of bergs taking path c that ultimately reach southward along branch i.

In order that the reader may have an idea of the comparative value of the year 1927 with respect to the number of icebergs that

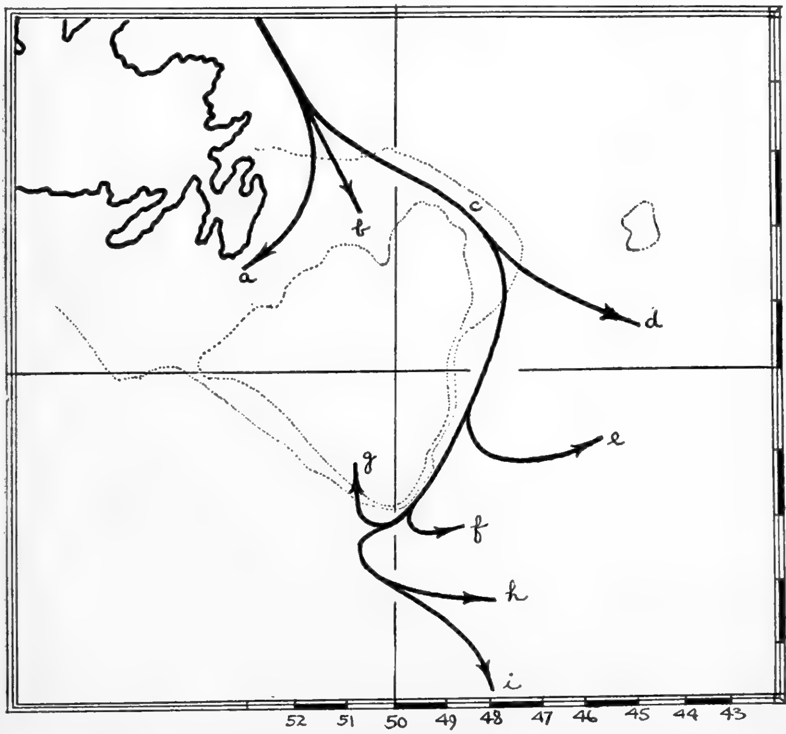

FIG. 30.—The main paths that icebergs are most liable to follow in the western North Atlantic when advancing southwards toward temperate latitudes. Branches d, e, f, g, h, and i are variations in the drift, once a berg has embarked along path c. This illustration is purely diagrammatic but it contains information where bergs are most liable to be met

drifted south of Newfoundland, there is appended below a graph of the iceberg character of the years 1880 to 1927, inclusive, arranged on a basis of 0–10. For a detailed count of the icebergs from 1900

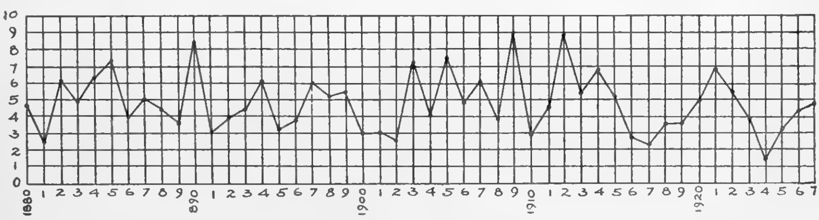

FIG. 31.—The iceberg character of the years 1880–1927 based on a scale of 0–10 mean value 4.8

to 1926, and also the departures in numbers from normal, please refer to Ice Patrol Bulletin No. 15, for 1926, pages 75 and 76. The iceberg character of 1927 is 4.8.

OCEANOGRAPHY

The fact that practically all the icebergs that drifted south of Newfoundland in 1927 remained to break up on the northern part of the Grand Banks, and that at no time during the season did ice threaten the United States-Europe steamship lane routes, gave the patrol more than ordinary opportunity to conduct frequent surveys of the ocean along the junction of the Gulf Stream and the Labrador

FIG. 32.—Oceanographic stations during 1927

current. We were thus able, during 1927, to follow more closely than ever before the processes that are continually altering the movement and behavior of the water masses in this interesting area around the ocean slopes of the Grand Banks. The state of the circulation resulting from the juxtaposition of the Gulf Stream and Labrador current, we have grounds to believe, is in successive months or weeks, never exactly the same, nevertheless there is an unmistakable tendency for the two antithetically charactered masses to

PLATE V.—THE FIRST BERG TO BE SIGHTED BY THE "MODOC" APRIL 11, 1927, LATITUDE 42° 43′ N., LONGITUDE 49° 45′ W.

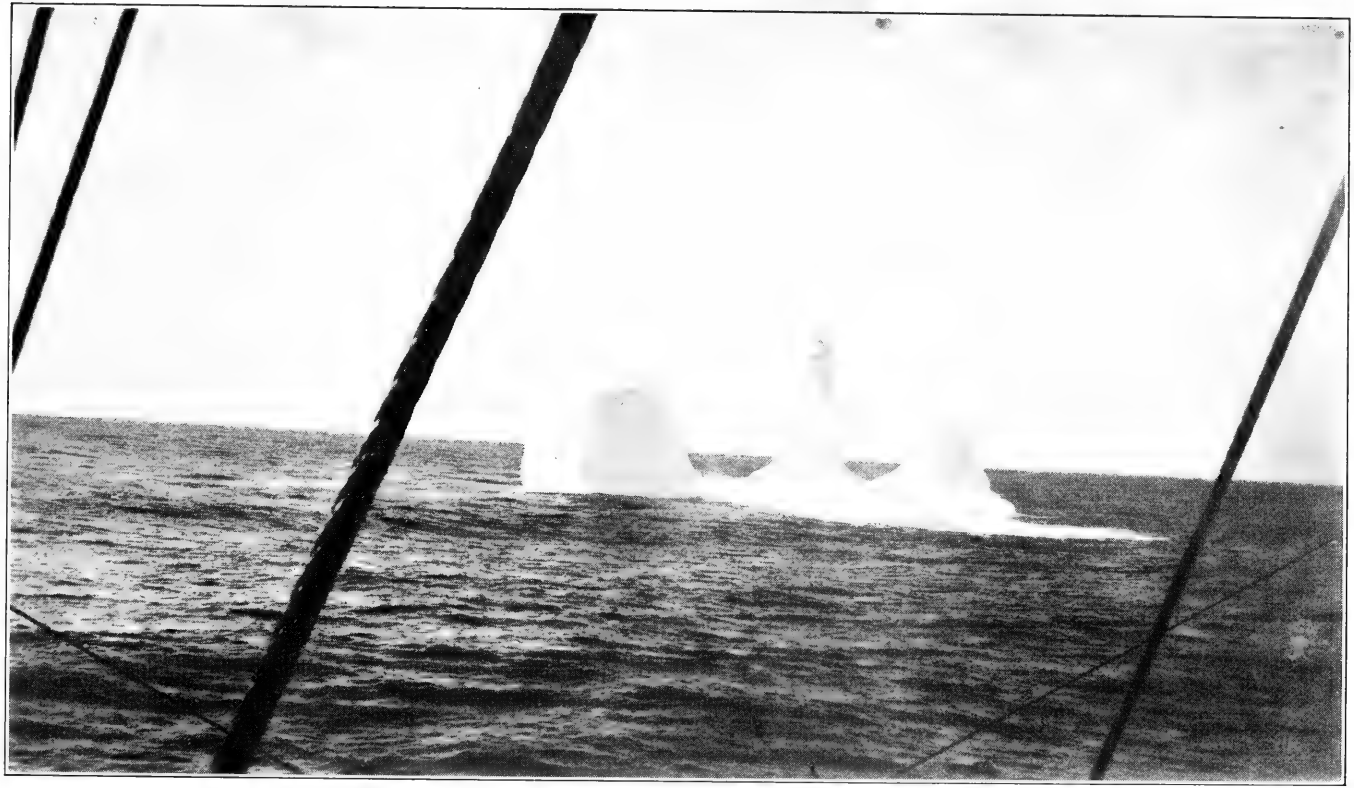

PLATE VI.—BERG ALONGSIDE THE "MODOC" APRIL 16, 1927, SHOWING PRONOUNCED EROSION FROM ACTION OF SEA AND HIGH TEMPERATURE OF WATER

occupy positions which are more or less characteristic for the Grand Banks area. It is natural to speculate whether daily synoptic data for the ocean depths would show short-lived movements, similar to those that form in the atmosphere. The ice patrol, however, is almost exclusively concerned in the extent to which major changes in the circulation cause a deviation in the iceberg drifts. And this information, we find for all practical purposes, is contained in the current surveys, obtained monthly or bimonthly.

In carrying on the scientific investigations, the ice patrol follows a program laid down by the ice patrol board which deals with its general policies and plans. First, our principal concern during the particular ice season is tracing the developments in the circulation from March to July, as governing the drift of bergs approaching the southern end of their transit. For example, the observations taken by the patrol in the first part of April, 1927, indicated the scheme of circulation around the Tail of the Bank depicted on Figure 34 p. 75. And the correctness of this picture is evidenced by the fact that on April 10 to 15 a berg drifted southward, swung around the Tail, and stranded in on the Bank, in conformity with the stream lines that had been calculated. In order to be prepared for future bergs in April, a second investigation of the waters was made April 21 to 25, which showed that the general scheme of circulation had slightly altered. (Fig. 38, p. 78.) No more bergs, it happened, drifted so far south as the Tail, but if they had there were data on board which would have been ample to predict their probable paths. Information on the ever-changing positions of the currents, it is plain to see, is of great value to the patrol in conducting its ice service to shipping.

The other aspect of the oceanographic work is one with a longer view, which, after a few more years' mapping of the currents, sees much information resulting from a comparison of the maps from year to year. We believe that there are particular features which are more or less characteristic of all years; types that are easily subject to classification. Already, for instance, we are convinced, as a result of current data collected even over a short period of years, that an area of approximately 1,000 square miles, located on the southwest slope of the Grand Bank, is normally the seat of an anticlockwise rotating eddy. This phenomenon (and it is important from our viewpoint) explains why bergs passing close by the Tail so often drift inshore and remain to melt in the shoal water on the Bank. Therefore, the greater the number of systematic surveys of the circulation, the better we are able to understand what formerly seemed a chance disposition of the ice.

There were five dynamic surveys made of the waters of the ice regions in 1927. The positions at which observations are usually made (C. G. Bull. No. 15, p. 87) were not adhered to closely in 1927, be-

cause experience now permits certain modifications in the program. Twice during 1927, for example, we were able to gain a good idea of the currents from a map based upon only 20 stations scattered net-like over the region around the Tail of the Bank. The other three surveys, however, dealt with a larger area situated along the eastern slope of the Bank, and consequently they embrace more stations than the earlier investigations. (See fig. 32, p. 70.) But the general plan of sections placed at right angles to the currents underlies all of the observational work. The choice of the particular area to be surveyed, it should be remarked, is often dependent upon the relative position of the ice and the patrol vessel, because we wish never to be far distant from the southernmost bergs.

A short description of the methods employed to determine the currents is given herewith. First we decide on the ocean area in which it is most desired to learn the direction and the velocity of the circulation. Usually the waters between the United States-Europe steamship tracks and the Tail of the Grand Bank are of first consideration, because it is there the course of the cold current and its freight of ice are subjected to the greatest variations in direction. When respite from ice scouting occurs, the patrol ship cruises over this zone; stopping and taking stations every 15 to 20 miles, the points of observation being distributed equidistant over an area which often approximates in size the State of Pennsylvania.

A thoroughly drilled oceanographic team of four to six men starts work when the vessel becomes stopped at the observation point. As soon as the ship is "dead" in the water, a heavy weight attached to a small wire rope is lowered over the side and an instrument called a water bottle is securely clamped to the wire at the rail. The meter wheel, which records the length of wire run out, is next set at zero, the winch brake released, and the line allowed to unreel rapidly off the drum. Six or seven water bottles are successively attached to the wire at those levels at which we desire observations, until we reach a depth of 750 meters, the limit to which the ice patrol has carried the work. A water bottle, it should be explained, is an ingenious mechanical instrument which, at the will of the observer, captures a sample of the sea water in which it is immersed and simultaneously registers the temperature by means of attached thermometers. When all the water bottles are suspended on the wire at the proper depths, a weight, called a messenger, is placed on the wire and, sliding down, trips the first bottle. This causes the instrument to automatically make a record and also release a second messenger which in turn slides down to the second bottle, and so the operation is carried on to the last bottle of the series. The wire is then reeled in, the thermometers read, and the samples of the water from the respective depths are bottled, the total elapsed time at a station being from 20 to 30 minutes.

The bottled water is next siphoned into the test cells of the electric salinometer, an instrument which conveniently measures the total solid salts of the sample per thousand grams of water. (See C. G. Bull. No. 12, pp. 136–147; and Bull. No. 15. p. 125.) There were over 1,000 samples of sea water tested for salinity by this instrument during the patrol of 1927. The next step is to convert temperature and salinity values into terms of specific gravity, and from these latter the currents are calculated. The final result of the current surveys are such sketches and maps as Figures 33 to 52. Such current maps, moreover, have proved of great value to those in direct charge of the patrol, as they reveal information on the probable movements of the ice.

The installation in 1927 of new electric oceanographic winches to lower and hoist the instruments materially shortened the time spent at stations, and thus allowed a greater number to be taken. A total of 208 stations, nearly double the number of any previous season, were located around the Atlantic faces of the Grand Bank.

The surveys were made in the following order: The first part of April the so-called critical area around the Tail of the Bank was surveyed. Two weeks later observations were repeated in the same region to determine what changes, if any, had taken place. The first part of May the *Modoc* investigated the water mass lying along the east side of the Bank from the forty-sixth parallel southward around the Tail and for a distance of 150 miles to the westward along the southwest slope. Three weeks later the currents were traced along the east side of the Bank by the *Tampa* for a distance of 120 miles north and south of a point on the slope where the warm offshore water pressed in. The final investigation for 1927 was conducted by the *Modoc* the second two weeks in June, and embraced the entire eastern slope of the Grand Bank from its northern reaches to the Tail and eastward to Flemish Cap. This was the most extensive survey ever conducted by an ice patrol vessel, and presented to those in charge of the work a most detailed picture of the ice and current conditions near the close of June. It was upon the information contained on the current map for this period that the strong recommendation to discontinue the patrol June 25 was based.

DISCUSSION OF THE CIRCULATION IN 1927

The total of 208 stations has, for the purposes of illustration and discussion, been divided into five groups or sets, arranged chronologically for the periods observed. Each set contains four maps—one dynamic topographic of the sea surface, one showing the direction and velocity of the currents as calculated, one representing the distribution of the cold and warm water, and one showing the relative positions of the fresher and salter masses.

Set I. April 6 to 10, 20 stations. (Figs. 33, 34, 35, and 36.)
Set II. April 21 to 25, 21 stations. (Figs. 37, 38, 39, and 40.)
Set III. May 10 to 18, 59 stations. (Figs. 41, 42, 43, and 44.)
Set IV. May 29 to June 3, 31 stations. (Figs. 45, 46, 47, and 48.)
Set V. June 9 to 25, 68 stations. (Figs. 49, 50, 51, and 52.)

The dynamic maps, Figures, 33, 37, 41, 45, and 49, show the topography of the sea surface compared to the 750 decibar (meters) surface, the assumption being that this plane was level. The numbers, viz, 728.80, 75, 728.70, etc., represent the height of the surface of the sea in dynamic meters above the 750 decibar base plane.

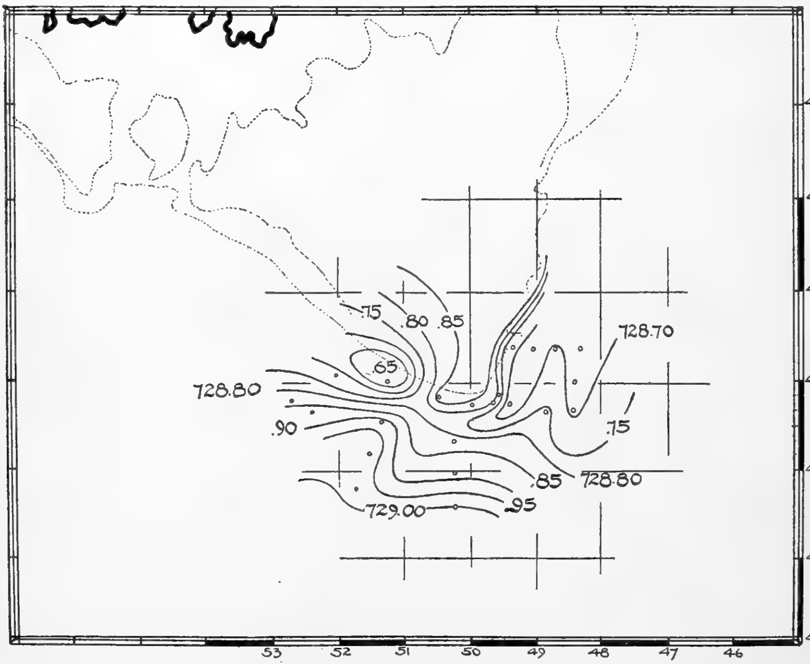

FIG. 33.—Set I. Dynamic topographic map drawn from observations made at stations 631–651, April 6–10, 1927. This map is read the same as an ordinary isotaric weather map

Such maps are quite similar to the ordinary isobaric weather maps, and, for all practical purposes, the dynamic contours represent the stream lines of the currents, as explained in Coast Guard Bulletin No. 14.

SET I

The oceanic situation April 6 to 10 may be described as consisting of an ellipitical depression in the sea surface centered over the southwest slope of the Grand Bank. From this center a trough extended to the eastward around the Tail, more or less paralleling the contour of the slope, and separating water of higher elevation, which lay in on the Bank, from that offshore to the southward. Figure 33 shows that the sea surface was highest at a point about 100 miles southwest

of the Tail, thus recording a slope of about 30 centimeters in a distance of 35 miles. Calculation of velocities shows that a rapid current of 1.4 knots per hour flowed toward the east at the outer stations along the southwest slope, and an equally strong set to the southward took place along the east side of the Bank about 45 miles north of the Tail. The current arrows on Figure 34 clearly show the manner in which the current hugged the 100-fathom contour to the Tail, where it split, one branch flowing for a short distance to the westward and then bending to the northwest to overflow the shallow part of the shelf. The outer branch turned abruptly

FIG. 34.—Set I. The direction and velocity of the currents, April 6–10, 1927. The drift of an iceberg April 12–15 is also shown

back to the eastward at the fiftieth meridian and joined the more voluminous masses of the Gulf Stream. Particular interest is attached to two features of the circulation which were in process when this picture was recorded: (1) a tendency on the part of the Gulf Stream, as shown in the shape of the current arrows, to force itself in toward the slope of the Bank; (2) the anticlockwise eddy seated over the southwest slope of the Bank, which appears to have received its life from the inner current on the north and also from the outer current on the south. In such a case it had a mechanical source rather than a hydrostatic cause. Its presence, however, was accountable for the only berg that reached the Tail in 1927, to be carried to the northwest, inshore, where it eventually melted. (See fig. 34.)

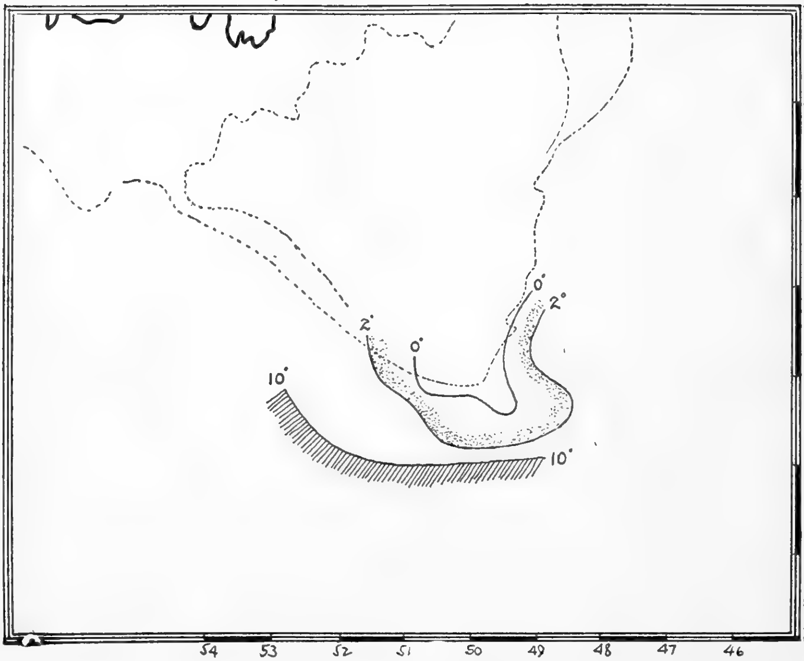

FIG. 35.—Set I. The distribution of cold and warm water at the 50-meter level, April 6–10, 1927

FIG. 36.—Set I. The distribution of salinity at the 50-meter level, April 6–10, 1927

The distribution of cold and warm water April 6 to 10, at a depth of 50 meters, is shown on Figure 35. We now see that the southerly drift along the east side of the Bank of 1.4 knots per hour must have been Labrador current because of its extremely low temperature. The much warmer water, greater than 10° C., which lay about 35 miles seaward of the continental edge was "Gulf Stream." The distribution of the salinity at the 50-meter level, as contained on Figure 36, supports the conclusions drawn from the foregoing figures of the set.

SET II

After an elapse of two weeks we repeated the survey of the area just discussed in order to determine what changes, if any, had taken

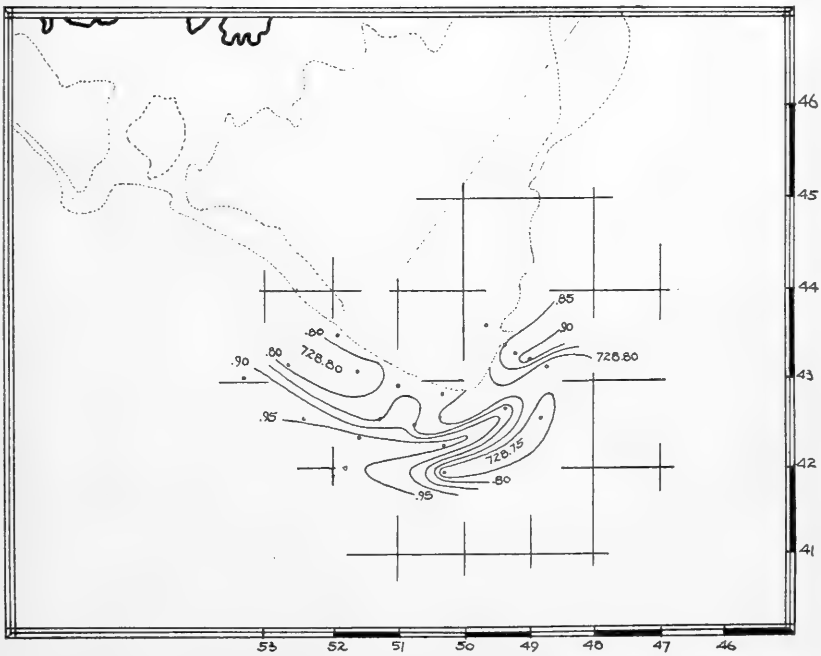

FIG. 37.—Set II. Dynamic topographic map drawn from observations made at stations 652–673, April 21–25, 1927. This map is read the same as an ordinary isotaric weather map

place in the scheme of circulation around the Tail of the Bank. We found the shallow depression in the sea surface still persisting in about the same position it had had two weeks previously over the southwest slope. A second depression, centered about 50 miles southeast of the Tail, was almost completely cut off from the Grand Bank by a ridge of relatively high contour, which had developed since the preceding survey, and was thrust from west to east, past the Tail between the forty-third and forty-second parallels. The surface of the sea on the eastern side of the Bank, between the forty-third and forty-fourth parallels, was elevated, the dynamic contour of 728.85

dynamic meters projecting in to the 100-fathom curve. The current velocities on Figure 38, when compared with those of two weeks previous (fig. 34) show a considerable slackening, except south of the Tail, where the outer current bent back toward the southwest at the very rapid rate of 1.7 knots per hour. There is also evidence that the outer current as a whole had pressed in more closely toward the slopes of the Grand Bank, especially on the east side of the latter, between the forty-fourth and forty-third parallels, where the cold water was probably dammed from following its usual path along the continental edge. The dynamic calculations in this instance are further supported by the drift of a large iceberg (fig. 38) first sighted by a steamer

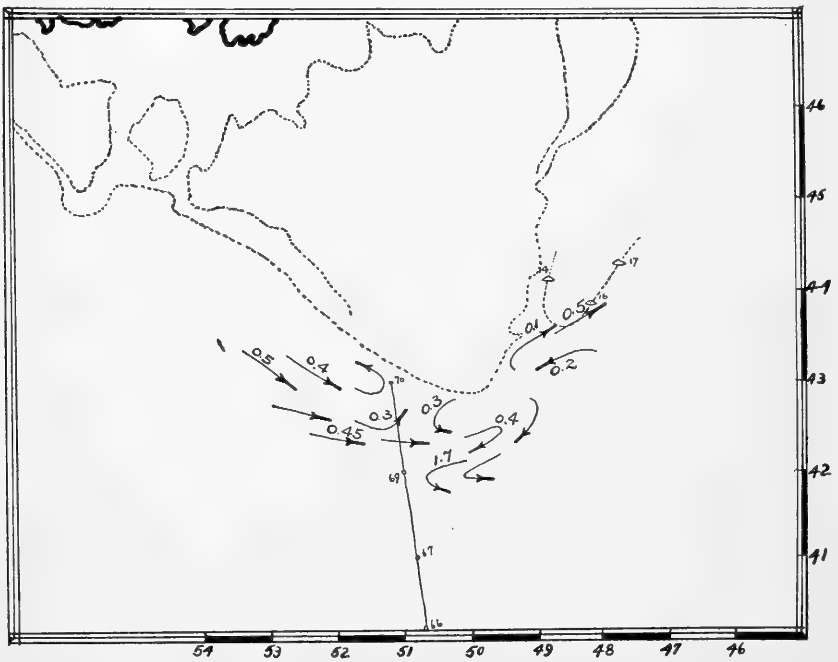

FIG. 38.—Set II. The direction and velocity of the currents, April 21–25, 1927. Numbers 66–70 represent a line of oceanographic stations taken by the "Michael Saro," 1910. See p. 80

on April 14 and then by the patrol on the 16th, and again for the last time on the 17th. Obviously its track agrees closely with the direction of the currents as calculated. It is also interesting that on April 16, a calm smooth day, we could plainly see tide rips about 2 miles westward of this berg. This must have been near the boundary of two currents (fig. 38), because later in crossing this zone we experienced an abrupt drop in the temperature.

Figure 39, when compared with Figure 35, shows that the temperature of the water around the Grand Bank grew much warmer during the month of April, except offshore from the southwest slope, where it had cooled somewhat. The distribution of salinity (fig. 40) in general corroborates the temperature chart for the same period.

FIG. 39.—Set II. The distribution of cold and warm water at the 50-meter level, April 21-25, 1927

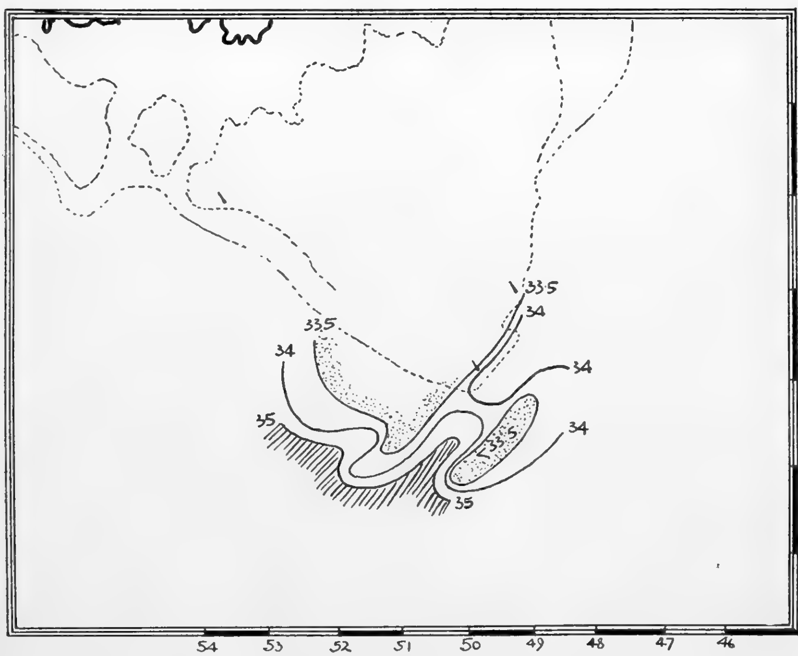

FIG. 40.—Set II. The distribution of salinity at the 50-meter level, April 21-25, 1927

The indentation south of the Tail of warm Atlantic water into the mixed zone and its counterflow toward the southwest, as shown on Figure 38, p. 78, brings to mind a similar condition found by the *Michael Sars* on a section across this region in 1910. (Murray and Hjort, The Depths of the Ocean, p. 99.) As a result of the observations of this expedition, the impression is often held that the Gulf Stream south of Newfoundland is split by a cold southwesterly current, but as such a phenomenon has seldom been observed the true condition has remained obscure. The ice patrol observed a similar location of the two currents south of the Grand Bank in 1923, but evidence in the form of surface temperature charts proved the cold current to be temporary and caused by the great irregularity and distortion of the boundary between coastal and oceanic masses. A multitude of curling tongues and votices is a natural accompaniment along the border of two opposing ocean flows, and our present-day ability to plot the stream lines of the currents reveals hitherto unsuspected phenomena concerning the behavior of the water particles. The fact that the course of the northern edge of the Gulf Stream south of the Grand Bank is found so extremely sinuous, turning and bending back so sharply upon itself, strikingly emphasizes the great mobility of water in the open sea.

SET III

This set of observations, taken May 10 to 18, extends the view from the neighborhood of the Tail, where the two former surveys stopped, to the circulation along the entire eastern side of the Bank. This is the first time that a dynamic survey has ever been made of this particular region. The axis of the depression previously observed off to the southwest of the Grand Bank was moved so much closer in to the continental edge, as shown by Figure 41, that the rising slope to be expected inshore of it no longer falls within the picture. Consequently no westerly current appears there, though such a set no doubt existed some few miles in on this part of the Bank. At the same time the extreme tip of the projection of high surface previously extending from west to east in the offing of the Tail had flattened out and the low pool to the southeastward had also shifted correspondingly to the westward. A second trough in the sea surface, as embraced by the dynamic contour of 728.70 dynamic meters, is seen on Figure 41 projecting offshore from the shelf for about 80 miles between the forty-third and forty-fourth parallels, and this formation is probably a development of the shoaler depression seen in the same general location on Figure 37. The ridgelike elevation to the north of it persists in extending southwestward, even abutting the 50-fathom curve of the Bank.

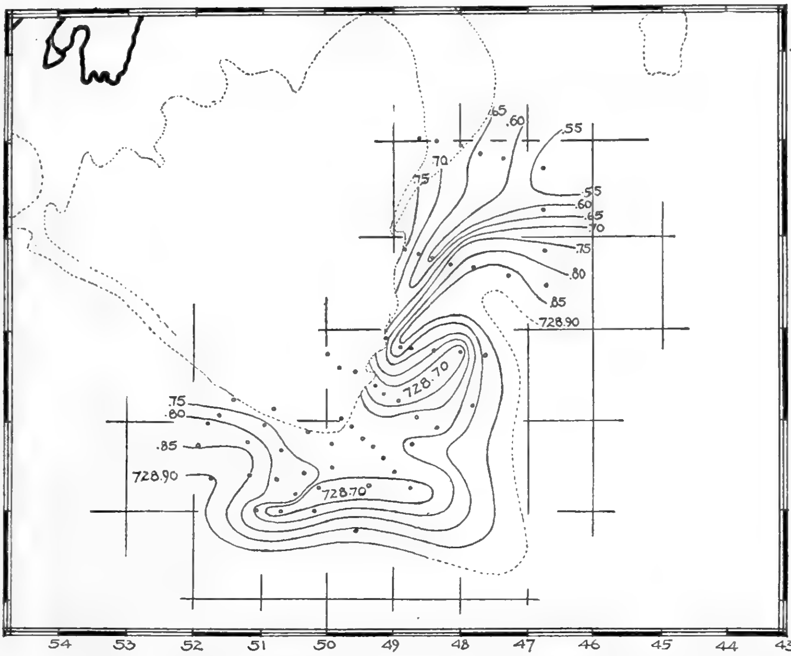

FIG. 41.—Set III. Dynamic topographic map drawn from observations made at stations 678–737, May 10–18, 1927. This map is read the same as an ordinary isotaric weather map

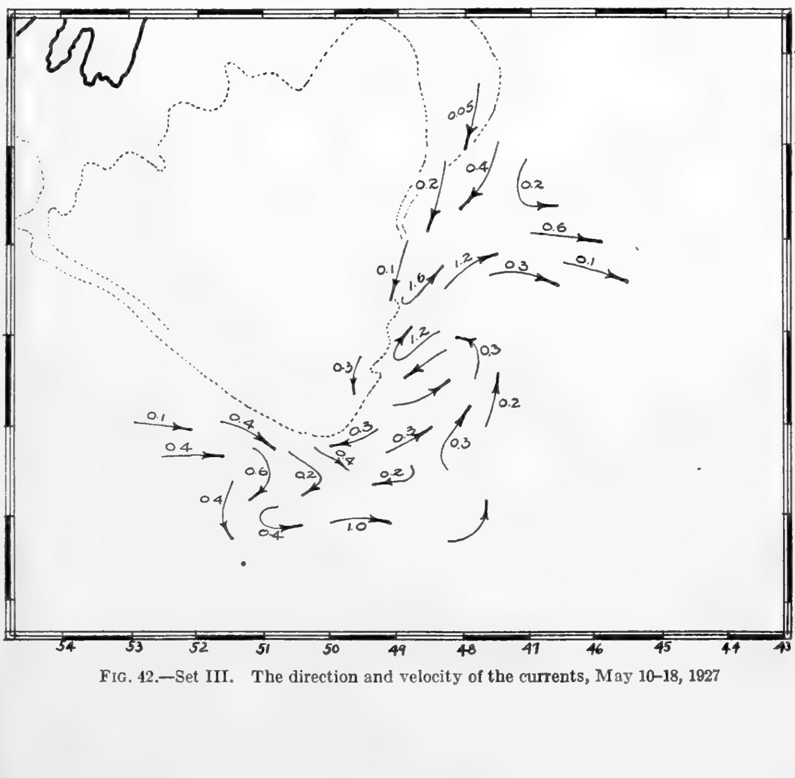

FIG. 42.—Set III. The direction and velocity of the currents, May 10–18, 1927

The currents resulting from the dynamic topography just described are shown on Figure 42. The outstanding feature of the circulation is the sinuous form of the outer current, swirling inshore quite markedly at two points along the slope—first on the southwest side of the Bank and later again on the eastern side near the forty-fourth parallel. The ice patrol has never before been able to secure such a satisfactory picture of the currents north of the Tail, as shown on Figure 42. Scanty records have led us to suspect, however, that the outer current often tends to pinch off the Labrador current and the supply of bergs, between the forty-fourth and forty-fifth parallels, more than at any other point along the slope north of the Tail. This locality is often the key to the ice situation.

After contemplating Figure 42, it is natural to inquire what causes the current to sweep inshore so much closer near the forty-fourth parallel than at other places around the Grand Bank? Let us approach the question by regarding the circulation over a wider area. The cause of flow of the Gulf Stream, for instance, has been the subject of great discussion among scientists, and one popular theory ascribes the motive power to propulsion imparted in the Caribbean. It can be proven, however, that if the water masses forced northward out of the Florida Straits depended solely upon their inertia of motion, the flow would entirely dissipate a quarter of the way to Hatteras.

The movement of the water particles along the eastern continental edge of North America is, we believe, on the other hand, chiefly a hydrostatic phenomenon caused by the mixing of coastal and oceanic water, forming thereby a heavy water zone. The sequence of events is as follows: First there must be two water masses of different salinity and temperature brought into contact. Under natural conditions the saltier mass freshens and the fresher mass salts. The warmer mass cools and the cooler mass warms, all with the important result that such a process creates heavier water than that which originally prevailed. This fact can be proven by taking equal samples, standard for each type of water, coastal and oceanic, around the Grand Banks as follows:

	Salinity	Temperature	Specific gravity
		°C.	
Labrador current	33.10	−1	26.53
Gulf Stream	35.20	13	26.56
Mixture	34.10	6	26.86

The density of the resulting mixture, 26.86, it is seen, is greater than that representative for either Gulf Stream or Labrador current.

Taking up the sequence again, we find that the water particles in the mixed zone, because of their greater specific gravity, continually tend to sink, but, due to the effect of earth rotation, actual movement is relegated to a lateral path more or less at right angles to the gradient. This, in brief, is the theory of marine currents in the region with which we deal.

The particular path an ocean current will follow, therefore, can be foretold provided the geographical position of dissimilar charactered water be known. The general distribution of coastal and oceanic areas, moreover, is governed to a great degree by the topography

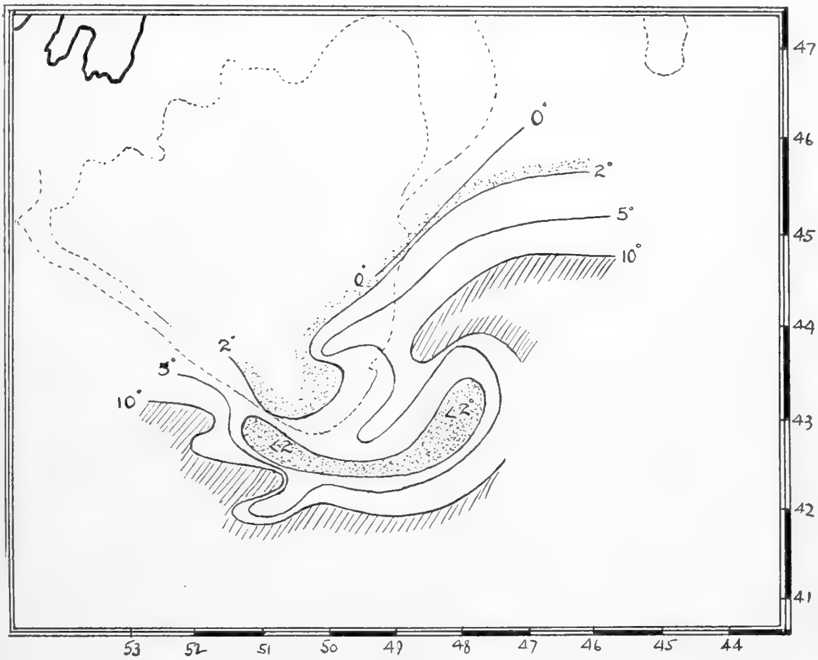

FIG. 43.—Set III. The distribution of cold and warm water at the 50-meter level, May 10–18, 1927

of the sea basin, and even where the depths are comparatively great we find their reflection in the physical character of the overlying masses. In this connection it will be observed that the Grand Banks after stretching out in a southeasterly direction from the Tail suffers considerable embayment near the forty-fourth parallel. Warm salty water is usually found filling this submarine valley, and near its head, which is close to the 100-fathom curve, we should expect to find the transition zone of the water and consequently the boundary between the currents.

The position of the cold and the warm water around the Grand Bank May 10 to 18 is shown on Figure 43. The two most interest-

ing features are the location and the shape of the elongated body of water less than 2° C. and the irregular inner edge of the warm offshore water as outlined by the 10° C. isotherm. The distribution of salinity at the 50-meter level (see fig. 44), when compared with Figure 43, indicates plainly that the water in closest to the Bank was Labrador current and the water farthest out in the basin was warm salty Atlantic.

The last week in May we searched along the eastern side of the Bank in the cold current and ascertained that there was no ice south of the forty-sixth parallel. Several bergs, however, were on the

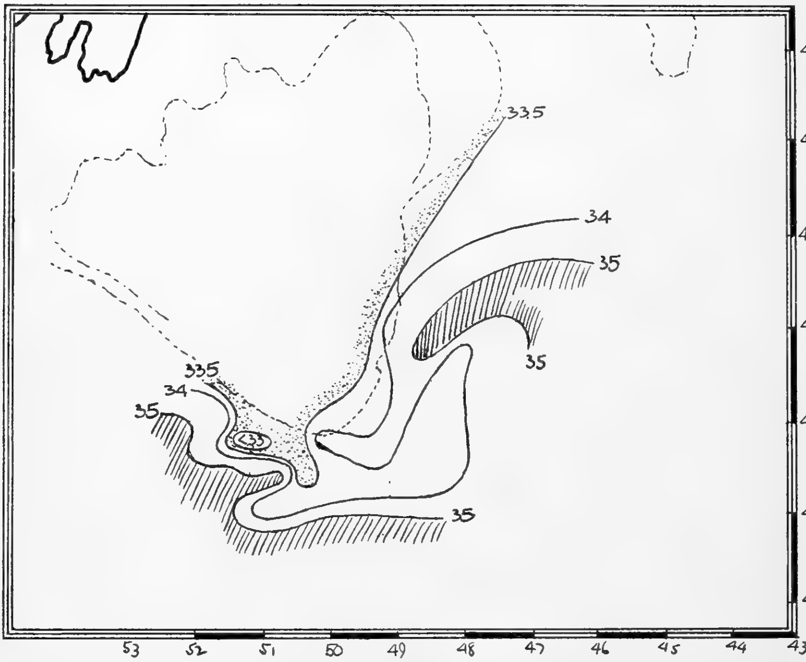

FIG. 44.—Set III. The distribution of the salinity at the 50-meter level, May 10–18, 1927

SET IV

northeastern slope, the largest group that had been in that locality during the season. It appeared probable, therefore, that they might drift farther south along the edge of the Bank, in which case a recent survey of the currents would be highly desirable.

Figure 45 is a dynamic topographic map obtained from investigations carried on May 29 to June 3, and is based upon a total of 31 stations. The striking feature of the picture is an elliptically shaped depression, as outlined by the dynamic isobath of 728.60 dynamic meters, which lay centered on the eastern side of the Grand Bank near the forty-fifth parallel. High aquain rose on all sides except to the north, in which direction a trough extended to the limit of the observations.

The circulation resulting from such a dynamic topography is shown on Figure 46. A current ran southward along the edge of the slope to the forty-fourth parallel, where most of it was turned back to the north, joining a countercurrent which swept in from offshore at this point. The inner edge of the countercurrent between the forty-fourth and forty-fifth parallels was only 30 miles seaward of the

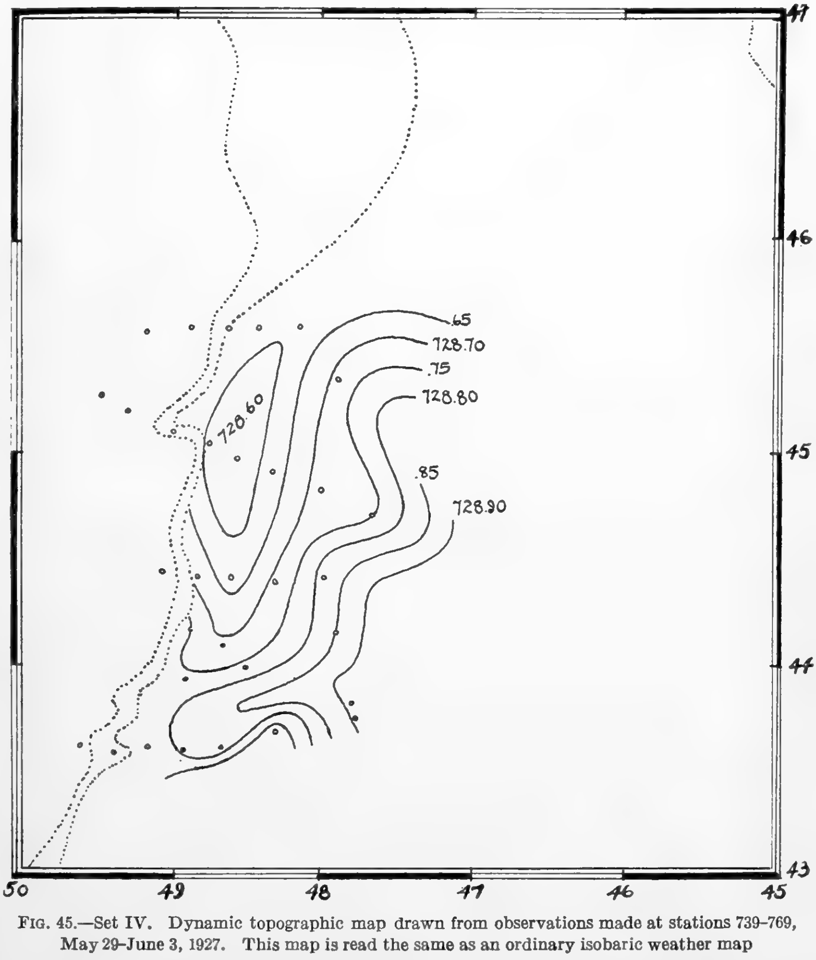

FIG. 45.—Set IV. Dynamic topographic map drawn from observations made at stations 739–769, May 29–June 3, 1927. This map is read the same as an ordinary isobaric weather map

100-fathom curve, but it later became deflected offshore just north of the forty-fifth parallel, and without doubt eventually passed south of Flemish Cap.

The form of the isotherms and the isohalines are unusually instructive when compared with the current arrows on Figure 46. The position of cold and warm water, also of the salt and the fresh masses, indicate the southward flow next to the slope to be that

known as Labrador current, while the current from offshore sweeping in toward the slope can be none other than Gulf Stream.

The most interesting event, at least from the standpoint of the patrol, was the presence of an iceberg which drifted in this area immediately after the completion of the current survey. It was first sighted on May 30 on the northeastern part of the Bank, and was seen again on the 31st, June 1, and the for the last time on the 4th,

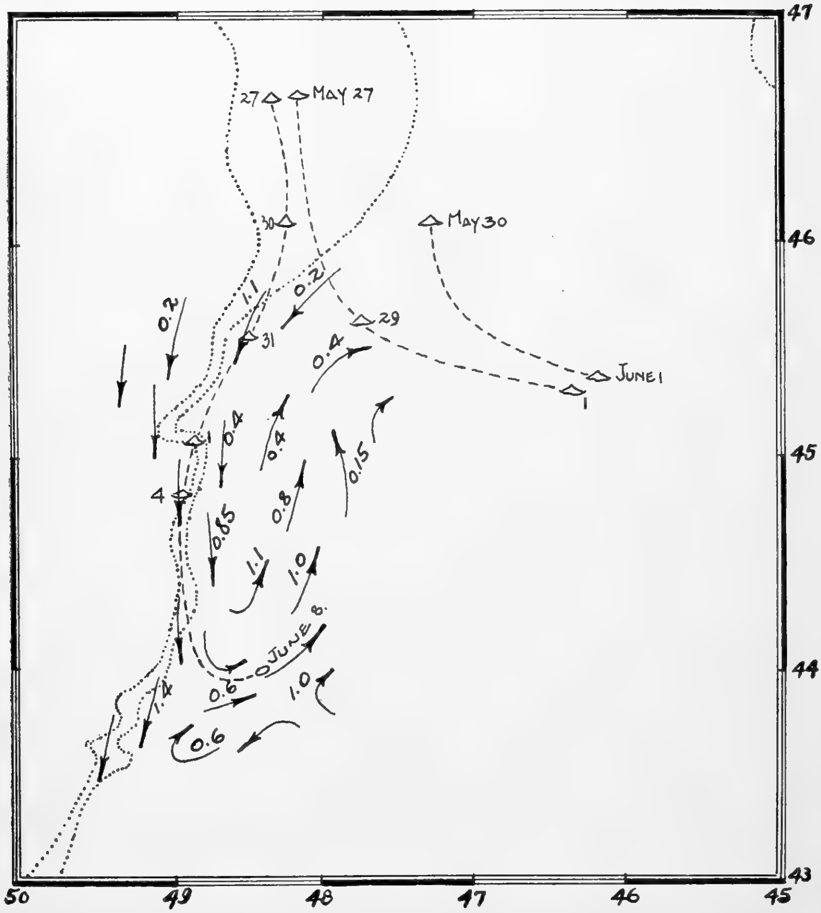

Fig. 46.—Set IV. The direction and velocity of the currents May 29–June 3, 1927. The track of an iceberg is shown from May 27–June 8, 1927, closely agreeing with the calculated circulation

when it was only the size of a growler. Its path, shown on Figure 46, closely conformed to the general scheme of circulation as calculated from physical observations of salinity and temperature. Its rate of drift also agreed quite well with the velocities as computed by Bjerknes's formulae. This is one of the best comparisons that the ice patrol has been able to obtain between dynamic equations and the actual drift of a floating object.

SET V

The last survey of the currents for the season of 1927 was begun June 9 on the northeastern slope of the Grand Bank near the forty-eighth parallel, and developed southward to the Tail, where it was completed June 25. A total of 69 stations were scattered fairly equidistantly along the east slope of the Bank and out into the basin as far as Flemish Cap. One station was taken well to the eastward of the others, offshore near the fortieth meridian, but it was used only

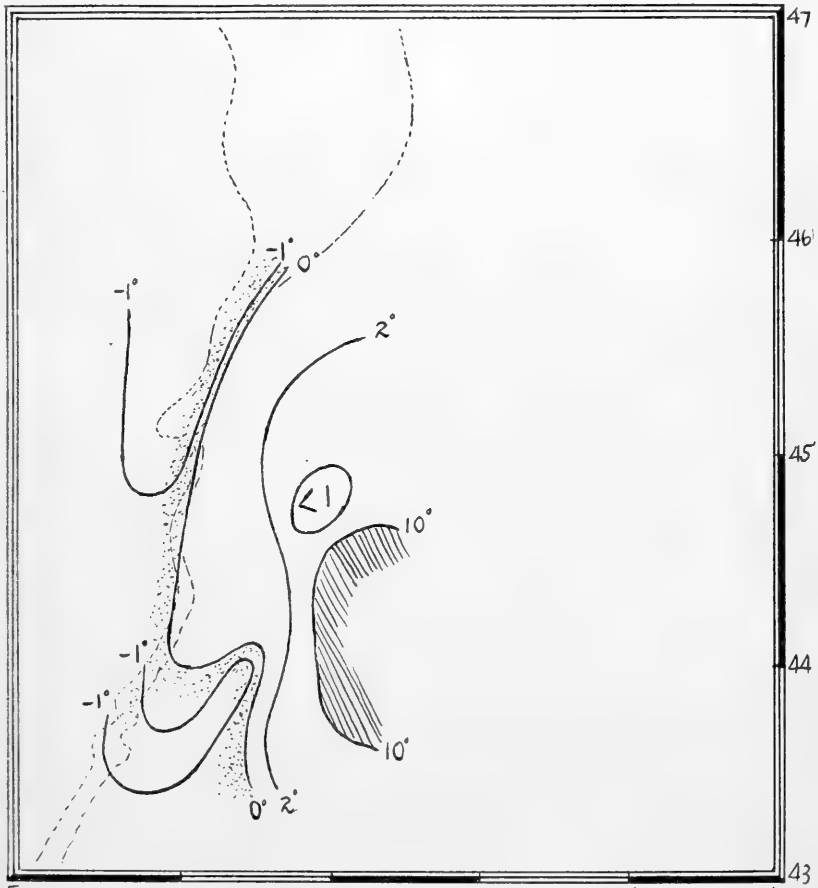

FIG. 47.—Set IV. The distribution of cold and warm water at the 50-meter level, May 29–June 3, 1927

for purposes of comparison with slope station data. The current survey made the latter part of June is distinguished from others because of the wider area it covers and also because it marks a pioneer investigation of the circulation between the Grand Bank and Flemish Cap. On account of the many shallow depths encountered in these

regions, it was impossible to employ a sufficiently deep common decibar plane, so in order to express the dynamic topography of the sea surface it was necessary to follow methods which give dynamic differences between adjacent pairs of stations. The figures, therefore, appearing on Figure 49 are expressed in terms of dynamic millimeters which are reckoned above a zero point located a short distance northeast of Flemish Cap.

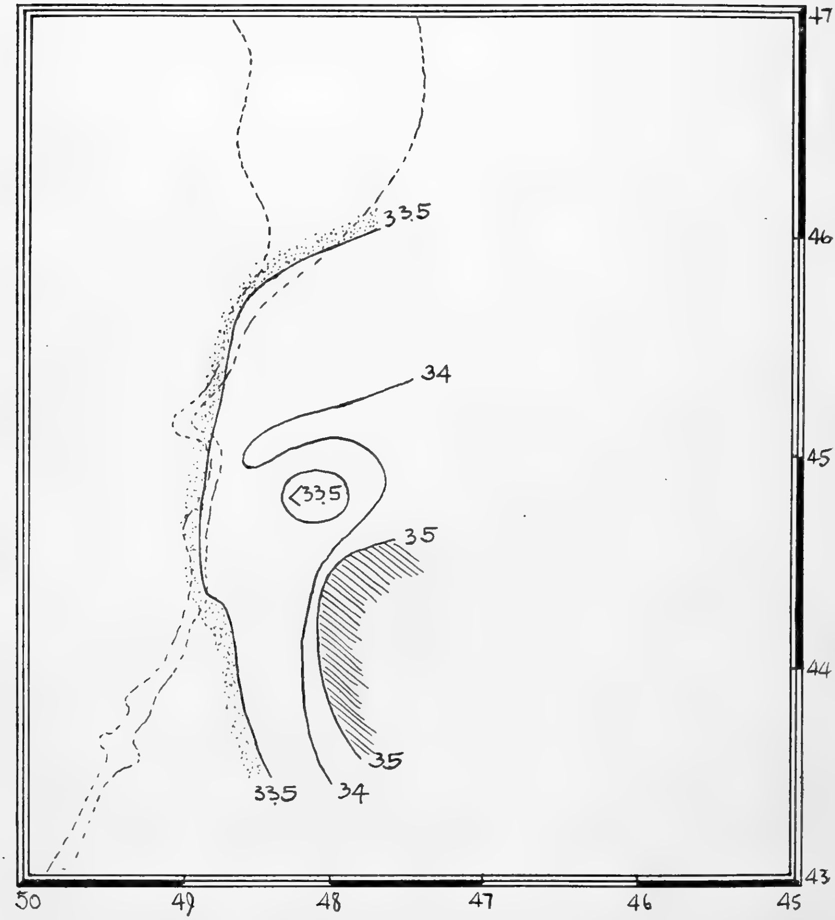

FIG. 48.—Set IV. The distribution of salinity at the 50-meter level, May 29–June 3, 1927

Figure 49 is featured by two general areas of high sea surface, one over the Bank and the other out in the deep water to the eastward. We took no observations over Flemish Cap itself, but in all probability they also would have shown the surface of the sea relatively high. On the other hand, a deep and narrow furrow lay stretched along the edge of the Bank between the forty-fourth and forty-fifth parallels, with the lowest point of the sea surface located north of

Flemish Cap at the outer end of our first line of stations. The surface was also moderately depressed over a relatively large area between Flemish Cap and the Grand Bank, and such a dynamic formation gave rise to northerly current on the west side of the Cap and a southerly set on the east side of the Bank. About 50 miles northeast of the Tail we located a comparatively small circular depression which gave the dynamic topography in this vicinity an odd appearance. The water between the 50 and 100 fathom curves, on the northeastern part of the Bank, where the slope of the bottom is

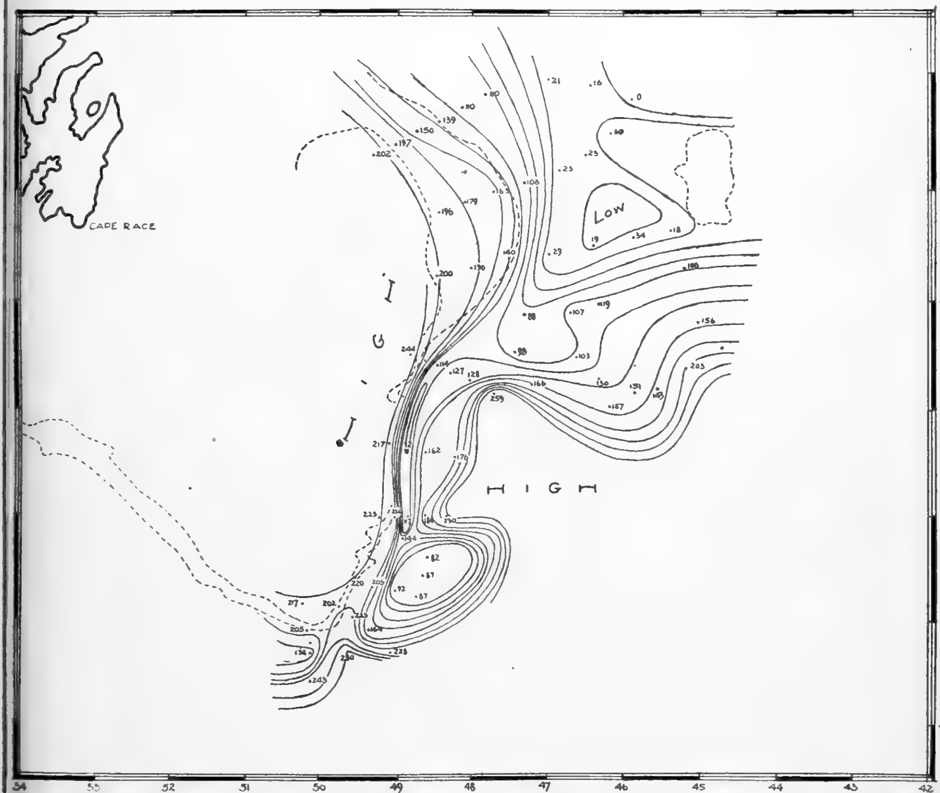

FIG. 49.—Set V. Dynamic topographic map drawn from observations made at stations 770–839, June 9–25, 1927. It is read the same as an ordinary isobaric weather map

gradual, formed the general limits of a wide gently flowing current, which, however, after crossing the forty-sixth parallel, narrowed and correspondingly increased in velocity. Sixty miles farther south the constriction became still further marked, and the rapid flow of 1.4 knots per hour was recorded between the forty-fourth and forty-fifth parallels along the continental edge. Casting our eyes farther south, we find the inner current, however, was apparently mostly all turned back before reaching the Tail, but lacking data from the southwest slope permits no definite statement.

The anticlockwise eddy seen on Figure 50, about 45 miles northeast of the Tail, is an excellent example of a process often to be found along the boundary of two opposing marine flows. We have noted before that when the Labrador current, which hugs the slope, becomes constricted and attenuated, no continuous, uninterrupted streaming of it can possibly prevail. On the other hand, it characteristically is broken up into a chain of eddies and regional circuits, distributed along the continental edge.

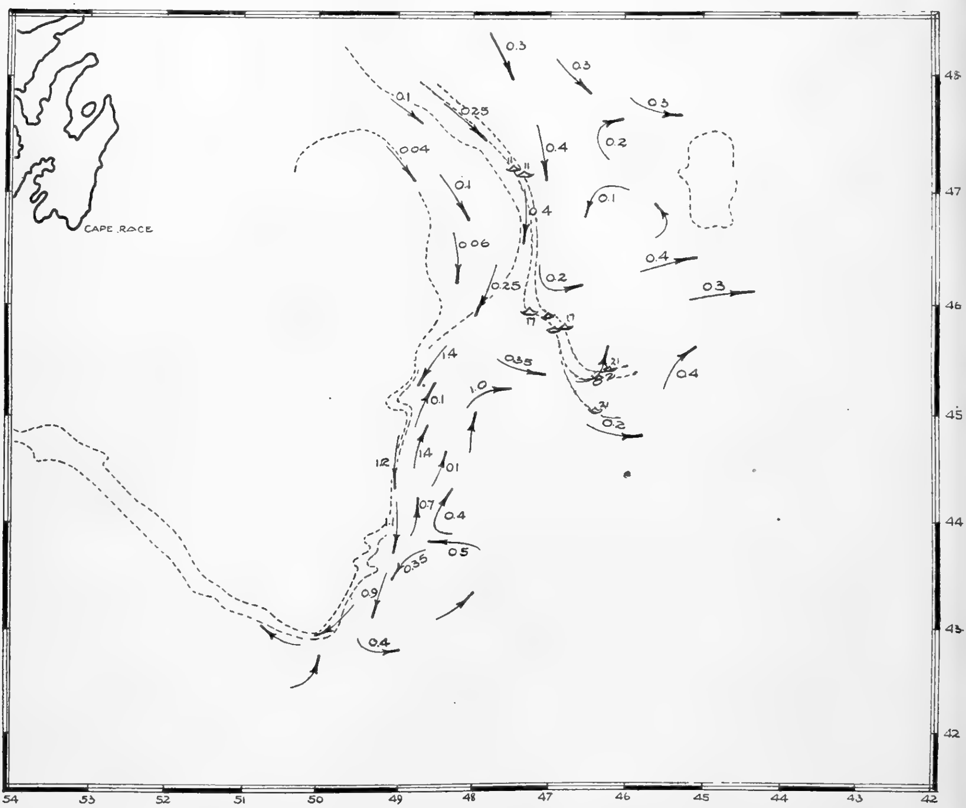

Fig. 50.—Set V. The direction and velocity of the currents, June 9–25, 1927. The drift of two bergs is shown from June 11–21, 1927

The outer current between the forty-fourth and forty-fifth parallels, June 9 to 25, swept in very close to the eastern edge of the Grand Bank, its inner edge at one place being only 5 miles in the offing. The current from there ran due north to latitude 45°, longitude 47° 35′, and then was bent back to the southeast, apparently by a discharge from northern regions between the Bank and the Cap. The outer current after passing this vent recurved toward the northeast, and finally proceeded out of our picture immediately south of Flemish Cap.

Examination of the temperature and salinity maps (figs. 51 and 52) plainly shows that the currents along the eastern slope of the Grand Bank were composed of two distinctly different types of water. The relatively cold and fresh masses which hugged the 100-fathom curve belong to the Labrador current, while the warm salty water flowing in the opposite direction was that commonly associated with the Gulf Stream. Along the boundary of the currents eddies and sinuous shapes characterized the general behavior.

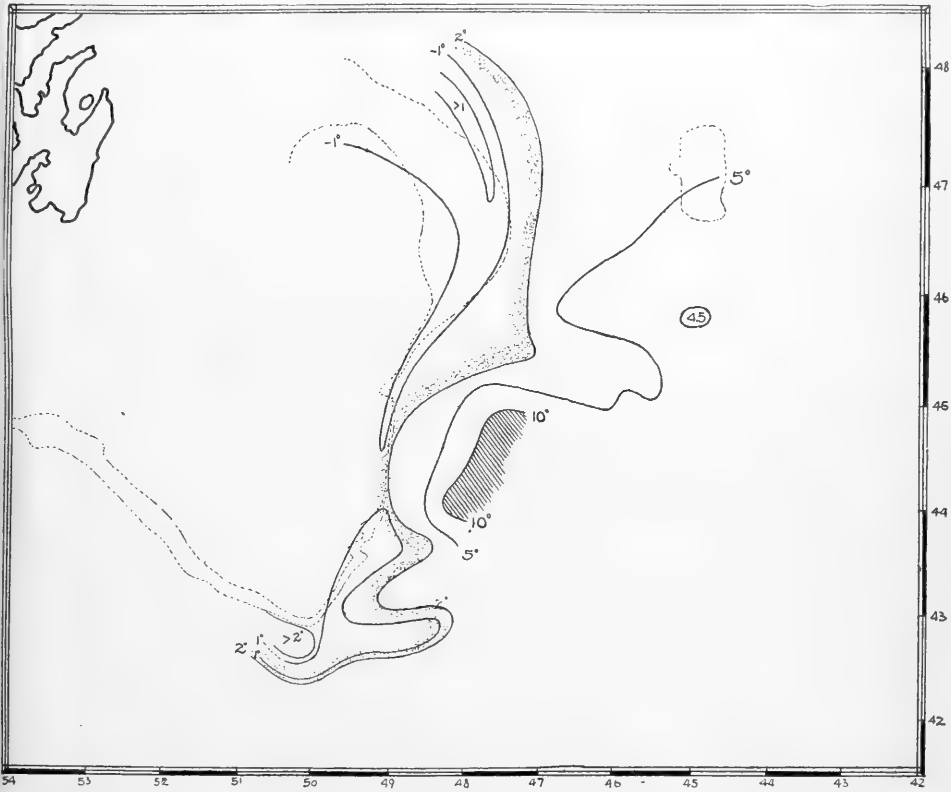

FIG. 51.—Set V. The distribution of warm and cold water at the 50-meter level, June 9–25, 1927

The patrol was especially interested in following the drift of two bergs which were sighted on the 11th of June floating in the Labrador current on the northeastern part of the Grand Bank. They were seen again on the 17th, 80 miles farther south, a drift which agrees very well with the velocity and the direction of the current as calculated and shown on Figure 50. The ice was sighted for the last time on June 21, having drifted southeasterly in the four days interim at the rate of 0.4 of a knot per hour. This set does not agree so well with the results obtained from observations in that locality, where the patrol found only a weak and variable tendency toward an easterly

circulation. The explanation of disagreement may lie in a sudden and transitory outpush of water from between the Grand Bank and Flemish Cap. The shape of the stream lines on the inner side of the Gulf Stream in this locality suggest such a possibility.

SUMMARY

The five current surveys which were made of the waters around the Grand Bank beginning the first week in April and ending the latter

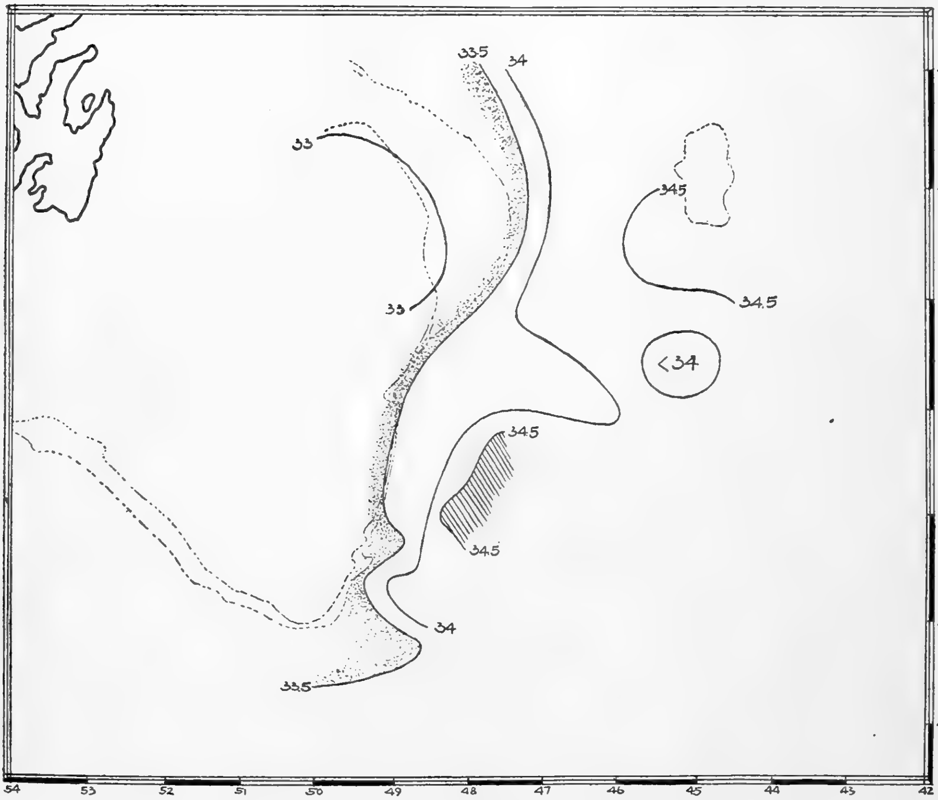

FIG. 52.—Set V. The distribution of salinity at the 50-meter level, June 9–25, 1927

part of June (and the five sets of illustrations, figs. 33–52) permit us to follow quite accurately the changes in the general circulation which took place during the ice season of 1927.

When the patrol vessel first entered the ice regions the circulatory system was basically normal, and by that is meant, Labrador current flowed southward along the eastern edge of the Grand Bank, while offshore the Gulf Stream moved eastward in the Atlantic. The counterclockwise eddy that the patrol has so often observed centered over the southwestern slope of the Grand Bank was sounded out and

charted soon after our arrival. The only unusual feature in early April was the wavelike form to the northern edge of the Gulf Stream southwest of the Tail, indicating a tendency of the warm current to invade the zone of mixed water. This particular feature developed during the latter part of the month, splitting the current, warm water lying both inshore and offshore of cold. We first observed the latter part of April that warm salty water was working inshore, up the submarine valley which lies near the forty-fourth parallel, on the east side of the Grand Bank. The outer current continued to encroach in toward the continental edge throughout the next two months, sometimes being pressed right up against the 100-fathom contour, effectively blocking any opportunity for ice to drift past. The outer current also swept northward along the eastern face of the Grand Bank as far as latitude 45° 00′ before it was completely deflected offshore passing south of Flemish Cap.

The Labrador current, on the other hand, during the last two months of the ice season was confined to a narrow stream along the east side of the Bank, which hugged the slope, was continually being turned back by the outer current, and seldom reached farther south than the Tail. The Labrador current tended to discharge at various times throughout the season considerable masses of cold water between the Grand Bank and Flemish Cap, and this fact is witnessed in the receding form to the inner side of the Gulf Stream where it passed this vent.

The foregoing facts mark 1927 as the first ice season throughout which the general behavior of the water masses at the junction of the Labrador current and the Gulf Stream has been accurately followed.

The drift of the icebergs in 1927, as might naturally be expected from the above, conformed to the developments in the circulation. Only one berg during the season succeeded in drifting along the normal path to the Tail, and that incident occurred before the middle of April. The few bergs that later were transported as far south as the forty-fourth parallel came under the influence of the onshore set, and either were swept to the westward into shoal water or were wheeled back to the northeast, along with much of the cold current.

As a result of the foregoing it is plain to see that frequent surveys of the currents around the Atlantic faces of the Grand Bank furnish an intelligent insight regarding the probable drift of the ice, and when carried out by the ice patrol such as in 1927, insures far greater safety to the trans-Atlantic steamships.

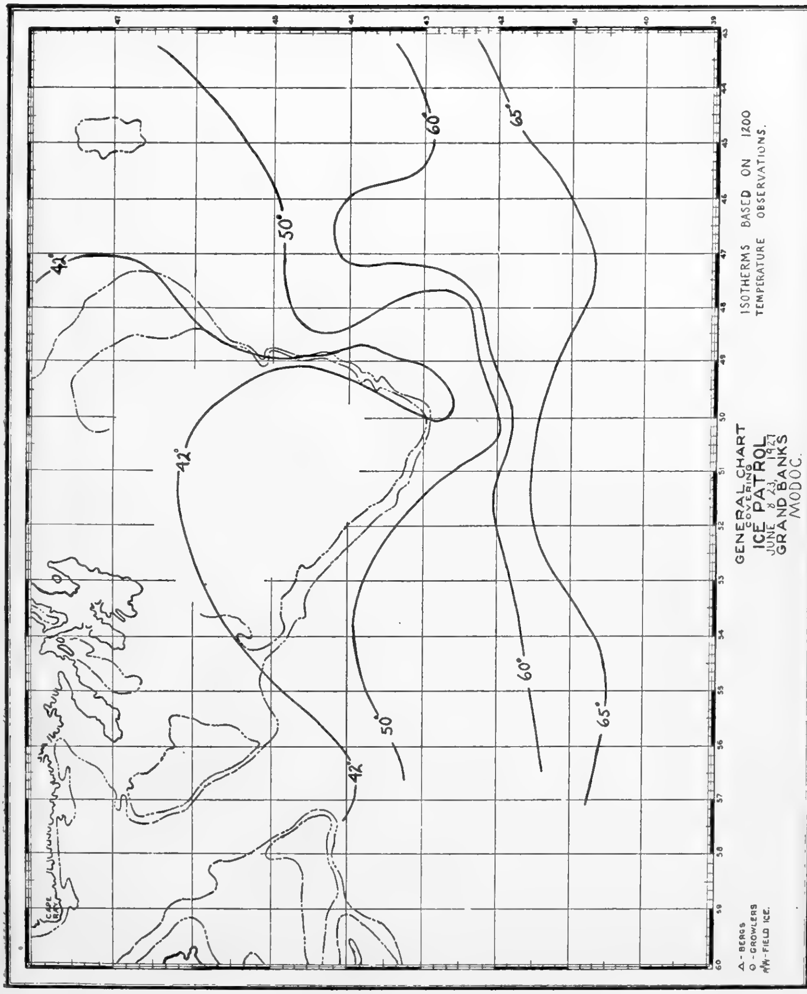

FIG. 58.—Surface temperature, June 8–23, 1927

OCEANOGRAPHIC STATION DATA AND DYNAMIC CALCULATIONS, 1927

δ_t at head of column 9 represents the value, density.
V at head of column 10 represents the value, specific volume in situ.
V–V₁ at head of column 11 represents the value, anomaly of specific volume in situ.
E at head of column 12 represents the value, height in dynamic meters.
E–E₁ at head of column 13 represents the value, anomaly of dynamic height.

Station	Date	Latitude	Longitude	a depth of water	a_1 depth	a = Meters: Temperature	a = Meters: Salinity 0/00	a = Meters: δ_t	a_1 = Pressure in decibars: V	a_1 = Pressure in decibars: V–V₁	a_1 = Pressure in decibars: E	a_1 = Pressure in decibars: E–E₁

THE INTERNATIONAL ICE PATROL

1928

The international ice patrol for the season of 1928 was carried out by the United States Coast Guard cutters *Modoc* and *Mojave*, with the *Tampa* acting as the stand-by vessel. Commander William H. Munter, in addition to being in command of the *Modoc*, was also in command of the patrol, as in 1927. Commander Cecil M. Gabbett was in command of the *Mojave*. Lieut. Noble G. Ricketts was detailed as scientific observer and remained at sea with two enlisted men as assistants throughout the patrol season, aiding the commanding officer of the vessel actually on patrol and keeping a continuous and uniform record of the patrol work for this annual report. Halifax, Nova Scotia, was the base for fuel and other supplies during the ice season. The *Mojave* and *Modoc* made alternate cruises of about 15 days each in the ice regions, the 15 days being exclusive of the 5 or 6 days occupied in going to and from base.

The duties and scientific work carried on by the patrol were, in general, similar to the practice during previous ice-patrol seasons. The objects of the patrol were laid down in the instructions issued by Coast Guard headquarters on February 29, 1928, to the commanding officers of the patrol vessels.

According to the orders the primary object was to locate by scouting and radio information the icebergs nearest to and menacing the North Atlantic lane routes, and to determine the southerly, easterly, and westerly limits of this ice by keeping in touch with it as it moved southward. Four radio broadcasts were to be sent out daily giving the whereabouts of all known ice in the vicinity of the steamer lanes. In addition to giving the location, the probable drift of the known ice was indicated when possible. Special messages were drafted and sent to any ship that inquired for special information relative to ice conditions, routes, weather, or similar matters. The successive positions of the water temperature and weather reports of the liners and other vessels were carefully watched, and whenever a ship was observed to be following a course leading toward danger the master was so advised, and routes or suitable precautions were suggested.

The secondary object of the patrol was to make scientific observations of weather, ice, and oceanic conditions. This work was imposed upon the ice patrol at its beginning in order that a greater knowledge might be had of the area about the Grand Banks, with special regard to the movement of ice. It is obvious that when more facts are known about the ice and its behavior, and the causes that lie back of

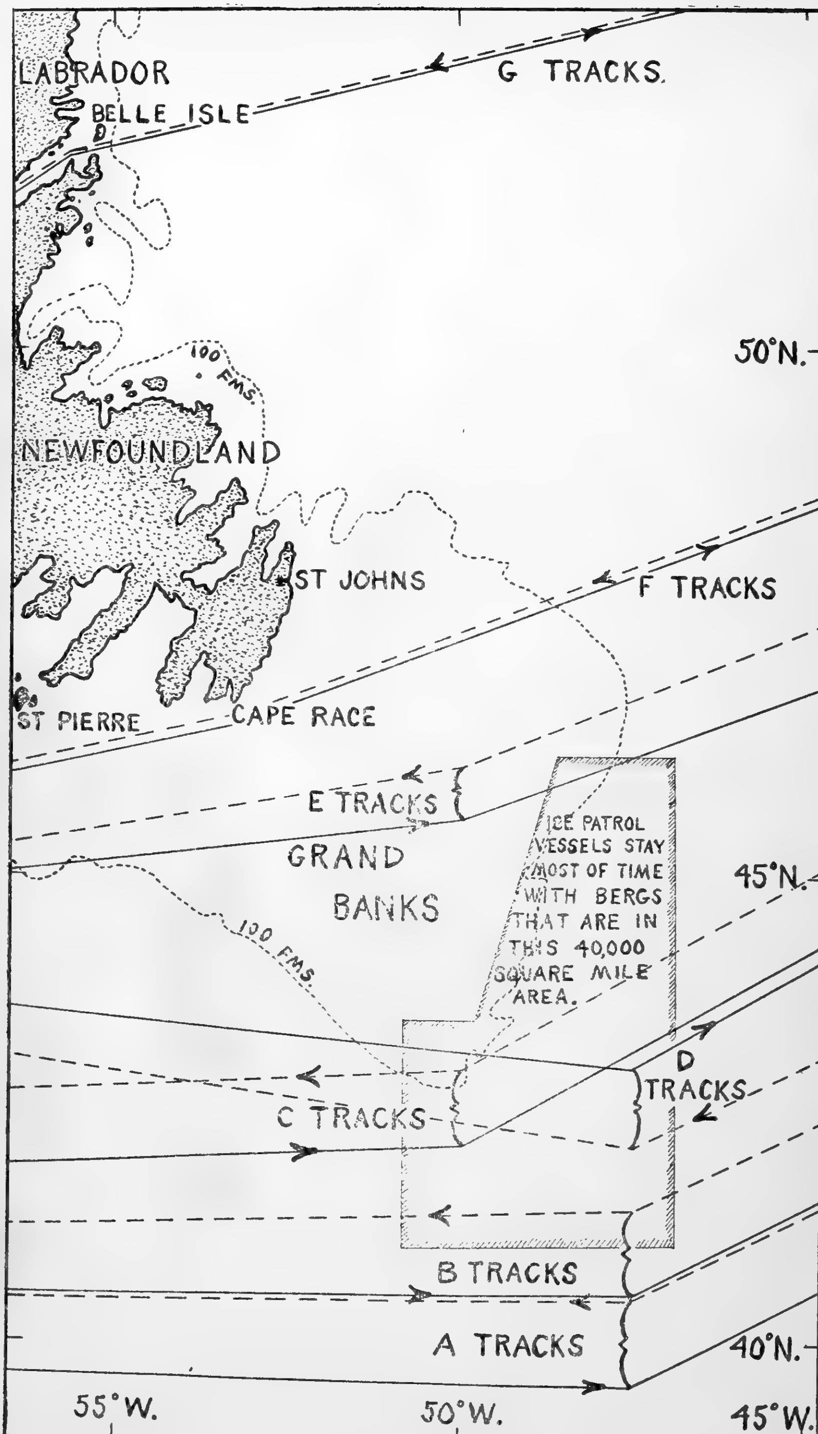

FIGURE 1.—Diagram of a portion of the principal North Atlantic Lane Routes. (For detailed explanation see next page.)

its marked variations in position and quantity from year to year, the more efficient a patrol it will be possible to maintain, and the greater will be the value of the service to shipping in general. The scientific and oceanographic work, being supportive and secondary in importance to the practical scouting and advisory work, however, was so arranged as not to hamper ice scouting and trailing.

The *Mojave* inaugurated the 1928 patrol on March 21, and from that date until the service was discontinued by a dispatch from Coast Guard headquarters on June 22, either that vessel or the *Modoc* was continually on guard in the ice regions.

Most of the vessels that ply between Europe and the United States and Canada do not follow the shortest route. That would be the great circle track and it would lead them, when plying between most ports, close past Cape Race, Newfoundland. On account of the well recognized ice menace, vessels have for many years followed established tracks, or lanes, that are shifted from time to time as the limit of the ice advances and recedes.

Figure 1 shows the approximate location of the different steamer lanes, and the explanation of the diagram shows when the different tracks are normally used. It is comparatively infrequent that the

---

EXPLANATION OF FIGURE 1

A, B, and C, are routes to and from New York.

D, E, F, and G, are routes to and from Canadian ports.

Eastbound tracks are full lines.

Westbound tracks are dashed lines.

For fuller information relative to the North Atlantic lane routes see the special track charts published by the United States Hydrographic Office and by the British Admiralty.

Inclosed area between tracks E and B about the Tail of the Grand Banks shows where the distribution of the ice usually keeps the ice patrol vessel.

Normal periods different tracks are used:

A, eastbound. March 25 to July 7.
A, westbound. April 1 to June 30.
B, eastbound. February 1 to March 24, and July 8 to August 31.
B, westbound. February 1 to March 31, and July 1 to August 31.
C, eastbound. September 1 to January 31.
C, westbound. September 1 to January 31.
D. February 15 to April 10.
E. April 11 to May 15 or until Cape Race Route is clear of ice, and December 1 to February 14.
F. May 16 to opening of Strait of Belle Isle, and to November 30, when not using Belle Isle route.
G. From opening of Strait of Belle Isle to November 14.

Above so called normal periods were taken from United States Hydrographic Office chart of North Atlantic steamship routes.

A tracks were not used at all during 1928.

B tracks were used from April 14 to September 1.

C tracks were used between United States and Europe throughout rest of year.

southernmost lane, called track A, is crossed by dangerous ice. During 1928 it is known to have been crossed by bergs only twice. The tracks to the north of A are progressively more dangerous, being especially so in spring and early summer, when the Labrador current strengthens and brings large quantities of ice down from the Arctic.

Those charged with the shifting of the tracks, and those concerned in any way with the navigation of ships along them, should realize to the full, in view of the many human lives concerned and on account of the enormous value of the floating property involved, their responsibilities in the matter, and act accordingly. The prevalence of fog and low visibility over the cold water areas where the ice is usually found makes the exercise of caution necessary.

During the 1928 ice patrol season the Canadian Pacific steamship *Montrose* struck a berg along one of the Canada-Europe tracks to the northeast of the area that is most closely guarded by the ice patrol. Although she stove in her bows with the reported loss of two lives, she was able to continue to her destination under her own power. While it is not desired to view the matter in a pessimistic light, it would appear that the increasing traffic along the northern tracks leading through areas where bergs are known to be normally present in considerable numbers, is liable to result from time to time in such collisions. The ice-patrol broadcasts, which list all the known ice, when they are coupled with good judgment on the part of masters and the exercise of caution at all times, will serve to reduce these collisions to the minimum, and should greatly mitigate their serious effects when they do occur.

CRUISE REPORTS

THE FIRST CRUISE, "MOJAVE," MARCH 20 TO APRIL 5

The *Mojave* left Boston, Mass., for the ice-patrol regions at 11.50 a. m. on March 20, 1928, in obedience to orders from Coast Guard headquarters. Westerly breezes and moderate seas were experienced until a position near the Tail of the Grand Banks was reached.

While en route to the patrol grounds on the 21st, the *Halifax* wireless officer, who has charge of all the important Canadian stations in the Maritime Provinces, was notified that the 1928 ice patrol was starting. His cooperation during the coming season was requested. On the same day broadcasts to shipping were sent out to the effect that the patrol was inaugurated and that reports of water, temperatures, ice and obstructions to navigation sighted, courses speeds, and positions, were desired every four hours from all ships in the ice patrol area, which was defined as lying between latitudes 39° and 49° N. and longitudes 43° and 56° W. This broadcast was repeated every four hours until March 23, and occasionally after that in order that all vessels might be fully informed regarding the patrol.

On the 22d, regular radio schedules with NAA, the naval radio station near Washington, D. C., were established in accordance with Coast Guard headquarters' instructions. On the 22d also the Cape Race radio stations and the French station at St. Pierre, Miquelon, were communicated with and requested to cooperate with the patrol vessel as in previous years.

A cyclonic disturbance passing to the north of the *Mojave* caused lightning and warm rains on the evening of the 23d. During the day about a dozen water temperature reports were received from trans-Atlantic vessels and plotted in on the cruise chart. As time went on the number gradually increased until each four-hour watch normally produced 15 such messages.

Morning of the 24th found the *Mojave* approaching the Tail of the Grand Banks from the westward. The whole day was spent in rectangular searching for ice that carried the vessel up to and slightly around the Tail. Strong westerly winds following the "low" of the night before raised a heavy sea. No ice was sighted and the night was spent drifting in the shallow water over the Tail.

At daylight on the 25th the search for ice was resumed up the eastern edge, but fog shut in around 2.30 p. m., when a "low" approaching from the northwest caused an indraft of air from the warm water to the southward to flow over the cold water in the vicinity of the Tail. The fog caused by these southerly winds lasted until

the night of March 28 over all the cold water areas about the Banks, a very unusual condition to persist for so long so early in the season.

The ice-patrol vessel took advantage of the time while balked from ice scouting by bad visibility to run two short lines of oceanographic stations off from the Tail toward the east. It was found that a considerable body of arctic water with temperatures as low as $-1.2°$ C. was situated off the Bank, but it was calculated from the formula in United States Coast Guard Bulletin 14, that this water was all practically stationary. This suggested that farther north there was some dynamic barrier to the free flow of the Labrador current down the eastern edge of the Bank, hindering the southward extension of cold water and ice.

The time during this foggy weather that was not actually consumed by station work was spent drifting over the Bank a little north of the Tail. This area was also north of the C tracks and so out of the way of the greater part of the trans-Atlantic traffic. The inactivity was useful in that it conserved fuel and insured that later on in the cruise there would be no enforced drifting during good weather due to lack of sufficient oil.

Visibility of from three to four miles on the morning of the 29th enabled the scouting for ice to be resumed. Throughout this day the *Mojave* searched to the northward up the eastern edge of the Grand Banks. The visibility improved as the day advanced, being good from noon until dark, As might have been expected after the lifting of the fog blanket, several reports of ice came in during the day.

The steamer *M. Christensen* approaching the Banks from the eastward well to the north of the patrol vessel, reported four bergs, growlers, and field ice. It is believed that the only reason more reports of ice were not received was because there were no other ships crossing the Labrador current to the north of the *Mojave*. That there was a large volume of traffic on the C tracks to the south was evidenced by the water temperature reports pouring in from that area, at the rate now of about 70 a day. If any ice had been near the traffic lane it would have been reported along with the surface temperatures. The total absence of ice reports from vessels to the south led the patrol to conclude that the proper direction to search was northward.

Late on the afternoon of March 29 the patrol ship sighted her first ice of the season, a growler in 44° 59′ N., 48° 39′ W. Shortly afterward a growler and a berg were sighted in 45° 15′ N., 48° 21′ W., and the *Mojave* was stopped to drift by the latter for the night.

The 30th was a perfect day for ice scouting, clear and almost calm, with springlike temperatures and a gentle rolling swell. On such a day the white bergs show plainly against the dark blue water and the

light blue sky to as great a distance as the curvature of the earth will allow them to be seen, usually from 15 to 20 miles for a masthead lookout. Speed had to be limited to 70 revolutions per minute, which gave between 9 and 10 knots, because of the continuing necessity for carefully regulating fuel consumption. A rectangular area to the northeastward was covered during the day and most of the ice reported by the *M. Christensen* was checked as to position and drift. The latter was found to be about 1 knot in a southwest direction.

Two new bergs were found just south of 46° N. and just east of the forty-eighth meridian. The berg left early in the morning was reached again before dark and was watched during the night. It drifted first to the southeast and then to the east, evidently having been checked in its southwesterly course by some such shoulder of the Gulf Stream as often presses in close to the Bank a little north of the Tail, so cutting off the flow of the Labrador current. Reports of relatively high temperatures from passing vessels gave further evidence of the existence of such a shoulder of warm surface water at the time.

Ice scouting was continued on the 31st, for the winds were as light and the visibility was about as good as on the preceding day. By noon it began clouding over, due to the approach of another "low" from the west. By 3.30 p. m. the weather was thick and rainy so the searching was abandoned. During the good visibility a considerable area to the westward to the 50-fathom curve had been covered and one more unreported berg had been located. A check up was also had on the westernmost berg reported by the *M. Christensen* on the 29th, which proved to have drifted due south at about 0.5 knot.

The night of the 31st the *Mojave* spent near the newest berg, which was believed to be the southernmost ice. During the night it was lost in the storm and fog, but the next morning was found by steaming about 10 miles to windward.

The 1st of April was spent near this berg in order to follow its drift. It was the largest berg seen so far during the season, measuring about 200 feet square and averaging about 30 feet high above the water line. All the bergs sighted so far had been rounded and water glazed except where sharp cliffs were in evidence—in some places about the sides, where overhanging projections of ice had calved off.

At 4 a. m. on the 2d the patrol vessel stood to the southward to take a line of stations from a point in the warm current in toward the Bank. Seven stations were taken down to the 750 meter level during the day between the forty-eighth and forty-ninth meridians in latitude 44° 27′ N. They showed a gradual cooling of the surface water from 7° to $-1.1°$ C. as the Bank was approached. A calculation of these stations determined the comparatively narrow width of the south-flowing stream and its approximate speed at the time and place.

To menace the United States-Europe tracks it was necessary for the ice to pass down through the narrow straitlike formation of cold water lying just off the eastern edge of the Bank. It is obvious that the narrower the band of cold water remained the easier it would be to watch and the fewer bergs would flow along it, other things being equal.

From her water temperature reports of April 1 and 2 it was noted that a steamer had passed only about 5 miles south of the southernmost berg. Steaming, as she apparently did from her successive positions, at a speed of 16.5 knots by it on a pitch dark night, it was deemed that her action was most foolhardy, especially so in view of the many factors of error that are possible in determining the position and drift of ice, and the possibility of the existence of ice not sighted or reported.

April 3 was another day of perfect visibility and light breezes like the two preceeding days. A final station was taken early in the morning on the 100-fathom curve near where the vessel had been drifting for the night. Then a run was made to the northeastward to locate ice before starting west to meet the *Modoc.* Three bergs and five growlers were sighted during the day. No less than 10 bergs were reported to the east and northeast of the Bank.

An abnormally high barometer prevailed, with gentle to moderate westerly breezes. On the morning of the 4th the wind had freshened from the west but the search was resumed at 7 a. m., and during the day the *Mojave* worked first to the westward, and then to the southward down the eastern edge. Only one berg was sighted during the day. None were reported. At 7 p. m. the vessel's head was turned to the southwest across the Bank towards the *Modoc,* which vessel was now rapidly approaching the patrol area.

During the first patrol cruise 38 ice reports were received from vessels and shore stations. Special ice information was sent on request to three steamers. There were plotted in all on the base map over 1,050 surface water temperature observations, 100 of which were made by the patrol vessel and the remainder received by radio from 130 different cooperating vessels.

The remarkable feature of the first cruise was the comparatively smooth seas and fine weather enjoyed most of the time. Except for the crisp air that almost invariably remained in the thirties and lower forties one might well have thought that the season was summer instead of early spring. One period of fog early in the cruise and two blustery but clear days were the only things that hampered the scouting and station work.

On the evening of April 5 the *Modoc* was met at a rendezvous in approximately 43° N., 53° W. There the oceanographic party was transferred and the relief of the patrol was effected by 9.30 p. m. As

soon as relieved the *Mojave* stood to the westward for Boston in accordance with authority received from headquarters on March 28. Permission to proceed to Boston instead of Halifax had been obtained because of the need of the fathometer for adjustment. The gyrocompass had broken down early in the cruise and was in need of overhaul also. The *Modoc* on taking the patrol duty over stood to the eastward toward the ice area.

THE SECOND CRUISE, "MODOC," APRIL 6 TO 21, 1928

When the *Modoc* sent a boat over to the *Mojave* to receive the oceanographic party at 9 p. m. on April 5, 1928, the commanding officer of the latter vessel took advantage of the opportunity to call on the commander, international ice patrol, on the *Modoc* for a conference. There was a light southeast breeze with a moderate northwest swell. Searchlights lit up the white patrol ships and helped the moon to illuminate the transfer activities. Mail, baggage, Navy moving picture programs, and several enlisted men were transferred from one vessel to the other.

The *Modoc* rounded the Tail about noon of April 6 and then started a search for bergs up the eastern edge. On the afternoon of the 6th and on the 7th and 8th perfect weather for scouting prevailed. The winds ranged from gentle breezes down to a flat calm, and the visibility was excellent. The heavenly bodies were practically always available for sights to locate the ship's position. Coupled with the radio bearings received at 6 a. m. and 6 p. m. from Cape Race and with the depths from the fathometer the sights made the position of the ship as certain as it could well be in an area of conflicting currents.

A large rectangle 50 miles wide and 80 miles long up the eastern edge was combed over for ice. That none was seen can be taken as conclusive evidence that there was none there. The southernmost bergs sighted by the *Mojave* had either been curved off to the northeast by the press of Gulf Stream water that was eddying in toward the bank around 44° 30′ N., 48° 30′ W., or forced inshore onto the Bank lower down by the same influence. Twilight and dawn fixes showed on the 6th and 7th the tendencies for night drifts to set to the westward when over the Banks and to the northeast when farther offshore.

On the afternoon of the 8th, about an hour before sunset, three French fishing vessels were intercepted on their slow way to the fishing grounds north of the Tail. The easternmost of them proved to be the barkentine *Bengali* of St. Servan. This vessel was given its position. It was circled and photographed while it put off a dory with mail to be posted. The *Bengali* was already 30 days out from France. She was reported to the French radio station at St. Pierre,

Miquelon. Shortly after this vessel was left a fog bank to the westward was entered. Immediately the *Modoc* stopped, to drift for the night, further searching being useless.

The three days of high barometer and fine clear weather were followed by a falling barometer accompanied by southerly winds and dense fog. This was plainly due to the passage over Newfoundland of the cyclonic disturbance that had been noted on the weather map for several days, making its way across the Mississippi Valley, the Lakes, and the St. Lawrence regions. It was so far away that the strongest winds experienced by the patrol were only force six from the south. These occured on the night of the 8th a little after the lowest barometer reading of 29.83 was noted. Up at Belle Isle at this time the barometer read 29.24. The patrol vessel had escaped another storm almost untouched on account of being well to the south of the storm track.

During the fog on the 9th four oceanographic stations were taken between the forty-eighth and forty-ninth meridians in latitude about 44° 30′ N. The patrol vessel steamed at slow speed, about 50 revolutions per minute, to the westward between stations. It was thought that the westernmost station would be in the shallow waters over the Bank, but, due to the easterly drift during the night of the 8th while offshore, it was found that the fourth station was located on the 1,000-fathom curve. After it had been taken the vessel was forced to drift by the approaching darkness. The stations served not only to indicate the dividing line between the cold and warm current, but also to familiarize the boatswains mates and the seamen of both watches with what was expected of them during station work.

On the 7th and 8th, reports of ice were received from vessels on the westbound C tracks in the neighborhood of 44° 30′ N., 46° 10′ W. These tracks were considered dangerous in consequence, and a special broadcast so stating and giving the reported positions of the bergs was sent out several times.

During the night of the 9th the fog cleared as the wind hauled more to the westward. An area of high pressure was noted on the weather map off the Middle Atlantic States, indicating a short spell of good weather for the ice-patrol area.

At sunrise on the 10th the patrol vessel began standing due north up the heart of the Labrador current. At noon the course was changed to 44° true in order to run along about 10 miles outside of the 100-fathom curve of the eastern edge. In spite of vigilant lookout and good visibility no ice was sighted until 3.30 p. m., when a large berg was observed nearly dead ahead and about 10 miles off.

This berg was the first glacial ice that many on board the *Modoc* had seen. It was a stable looking berg with old water lines and much mass. There was one pyramidal pinnacle that was separated

by a wave washed trough from the main plateau of the berg. It was circled and photographed but a snow squall came up at this time and prevented the getting of good pictures.

The northeasterly course was continued. After running about 12 miles another berg was reached and drifted by for the night in 45° 58′ N., 47° 46′ W. While running between these two bergs a whale was collided with. Being struck a glancing blow no perceptible jar was felt on board, although the large creature was rolled over and seen to scrape along the ship's side.

The 11th was spent running to the southeastward and eastward before a fair wind to investigate bergs that were being continually reported along the C tracks between the forty-fourth and forty-fifth meridians. One berg was sighted at about 11 a. m. on the port beam. Its position was cut in but it was not approached because it was not the southeasternmost ice. On the morning of the 12th the search was resumed and the berg especially being looked for was found at 1 p. m. It was circled and used as a point of aim during general quarters. This berg was low like a monitor and much eroded. The water it was floating in was of a temperature of about 56° F. The swells were giving it such a good washing with this warm water that it was not expected to last long.

The remainder of the 12th was spent searching for ice to the southward. One growler was found, probably the remains of what had been reported by steamers as a berg for several days past. The first berg, being larger and much more dangerous was returned to and drifted by until morning.

During the night no less than three steamers were seen approaching on the courses that would have carried them close to the berg. They were warned by blinker and searchlight of its presence and all of them altered their courses and passed clear.

In the morning the berg was seen to have drifted to the southeast at about 0.7 knot. It was very small now and would not remain a menace to shipping many hours longer. Accordingly, at daylight it was left and a course was shaped to the westward through a different area than had been covered on the previous two days. No ice was sighted, but the berg left was reported twice during the afternoon by passing vessels on the C tracks. The last report placed it in 44° 11′ N., 43° 21′ W. It was never heard of afterwards, so must have melted entirely during the night of the 13th.

The 14th was a day of increasing easterly winds that reached fresh gale force in the afternoon. The course toward the Banks was continued before the wind. Three oceanographic stations were taken during the day in the warm water, but the wire slanted off to windward too much for accurate results.

At 1.30 p. m. the vessel was stopped and Titanic memorial services were held in the gale. No berg was at hand this year, but the rough sea and howling wind made a fitting background for the ceremonies observed on this, the sixteenth anniversary of the great marine tragedy that created the ice patrol. An account of these exercises was radioed to the press as in previous years.

On the 13th the *Modoc* received inquiry from the press relative to news concerning the German trans-Atlantic fliers. A double lookout was kept from aloft for sight of them. When it was learned that they had landed in the Strait of Belle Isle it was realized that they were too far away and beset by too much ice to be assisted by the patrol vessel.

On the 14th also the C tracks were ordered discontinued by the North Atlantic Track Conference. The B tracks were made effective, much to the relief of the patrol vessel. The unusual southeasterly drift of ice this year had menaced the more northerly C tracks for some days. Every broadcast for some time prior to and after the 14th contained warnings to vessels that the C tracks were crossed by bergs and that extreme caution should be used between the forty-second and forty-seventh meridians during darkness and other times of bad visibility.

While the *Modoc* drifted on the night of the 14th the wind backed to the north and then gradually moderated as the "low" that had passed near by moved further out over the ocean. The whole of the 15th was spent scouting in the mixed water just east of the Banks trying to locate again the southernmost bergs in the central branch of the Labrador Stream. These waters were noted to be of a brownish color like weak cypress water. The color was especially noticeable because of its contrast with the warm blue waters of the Gulf Stream drift that had surrounded the ship for the past three days.

At 5.30 p. m. two large bergs were reached in 45° 03′ N., 48° 22′ W. These were circled and photographed in the light of the late afternoon sun. A station taken just clear of the bergs showed that the water at all levels was above the freezing point. Gulf Stream influence, even here, was therefore apparent.

On the morning of the 16th it was foggy at times, due to the winds having shifted to the southeast. The two bergs were still in sight to the northeast during clear intervals, distant about 6 miles. A station was taken at 9 a. m. that showed the *Modoc* to have been blown during the night into purer arctic water. The temperatures at the surface and down to 125 meters were between $-0.6°$ and $-0.2°$ C. The day was gloomy and misty, altogether unsuitable for scouting, so 10 miles were run to the westward and there another station was taken in even colder water, probably near the axis of the

Labrador current. When this station was finished a berg about 5 miles to the northwest was approached and examined.

This one proved to be a large picturesque berg. The blue tints and streaks in the ice were very striking. Peaks at two ends were seen to be cracked and apparently ready to fall, but whistle blasts and the reports from several blank 6-pounder charges failed to dislodge any ice. This berg was seen to have a distinct line of brownish yellow dirt in it as noticeable and as even as the caramel icing between the layers of a white cake. It was surmised that this was due to dust deposited on the ice cap in Greenland at some time in the past, possibly after a great volcanic eruption. The berg was very stable and had an old deeply worn-out water line around it, with spray glazed ice just above.

Three large birds, different from the regular species of sea birds about, were noted. These were perched on the high parts or on sheltered niches far up on the berg. When the ship got close they were found to be snowy owls that somehow had become passengers on this moving block of ice and been carried far from their arctic home.

A little to the westward a station showed only 32 fathoms of water. All of it was cold arctic discharge from $-0.6°$ to $-1.0°$ C. During the remainder of the day and throughout the night the ship drifted on the Bank in the rain. A gradually rising wind and a falling barometer were experienced.

Since the 10th many reports of ice had been coming in from steamers. No less than 17 reports were received on the 15th and one of these was from a steamer just northeast of the Banks that reported nine bergs along her course for the day. Two other vessels on parallel courses, 40 and 65 miles south of her, reported altogether 11 bergs during the day.

The ice had become much too voluminous to permit the listing of all the separate bergs in the broadcasts, so the practice of summarizing conditions in certain areas was resorted to. This expedient permitted the shortening of broadcast to practicable lengths. Whenever, as frequently occurred, ships would ask for special reports of ice along their courses their tracks would be laid down on the ice chart and messages would be immediately framed for their particular needs, giving the reported locations of all the bergs near their tracks.

On the 12th the *Montcalm* began the Canadian ice patrol in the Gulf of St. Lawrence. A day or two later the first steamer bound for the gulf and river ports was noted approaching the Banks.

By daylight on the 17th it was blowing fresh from the north, but the visibility was good. A search to the east and south off the Bank was made during the day. Three bergs were sighted in the deep water. On returning to the Bank for the night the two bergs

first sighted on the 16th were relocated and approached, to be drifted by until morning. The southernmost of the pair was now in 44° 52′ N., 49° 10′ W. It had drifted due south at about 0.5 knot for the past two days and was believed to be the southernmost ice. Considerable calving and erosion had taken place during the past 24 hours. One of the three snowy owls seen on this berg the previous evening was missing.

On the 18th the search for ice was resumed first to the east and then to the south down the Labrador current. No ice was sighted until toward evening, when two bergs reported earlier in the day by the *Berlin* as in 43° 43′ N., 48° 45′ W., were reached. Ice so far south was not expected. These bergs must have slipped down in the cold current during the *Modoc's* cruise to the eastward from the 12th to the 14th. During the night a rather severe storm of small proportions passed over, no doubt a secondary of the big "low" noted over Belle Isle.

During the blow several dovekies were picked up from deck in a stunned and bewildered condition from having been dashed against the deck house.

The two southernmost bergs were located again on the morning of the 19th and then approached and examined. Both were rather small and were drifting south about 12 miles per day according to radio bearings, dead reckoning, and soundings. Clouds prevented the accurate determination of position. A run was made to the south but no more bergs were sighted. The visibility was excellent after the storm. At 10 a. m. a course to the northwest was laid which was changed to the southwest for the Tail at 1 p. m.

After steaming about two hours on this last course, the masthead lookout sighted a berg three points forward of the port beam. It was headed for, proving to have been 15 miles distant when first seen. The berg was a solid low one that bore no resemblance to the dry-dock type whatever, being about 30 feet high and with cliff-like perpendicular sides. This berg was the southernmost ice sighted or reported so far this year, being in 43° 16′ N., 49° 14′ W. A southwesterly course was continued from the berg for 18 miles, when the course was changed to west for the Tail. The night of the 19th was spent drifting in the shoal water.

On the 20th four oceanographic stations were occupied, three of them over and one to the south of the Tail. Pure arctic discharge was observed at the bottom in the shoal water and down to the 125-meter level in the deep water to the south. At 2 p. m. the vessel was hove to on a WSW course on account of a SW gale with heavy swell.

The *Mojave* was met at 8 a. m. on April 21, 1928, in 43° N. 52° W., where the relief of the patrol was effected, As soon as the duty was turned over, the *Modoc* was headed for Halifax.

During the second cruise the weather was rather good on the average for the season until the storm of the 20th. Winds of gale force were experienced on seven different days, but lasted only about 40 hours in all, as the storms were of a very brief nature. The storm of the 20th was most inconvenient, for coming as it did toward the end of the cruise, the heavy swell remained to make the boating incident to relief of patrol quite nasty.

Visibility was good about 75 per cent of the time. Bergs were noted unusually far to the southeast and east during this cruise period. Altogether 123 ice reports were received from ship and shore stations. Special ice reports were sent out on request to 18 vessels. The isotherms on the cruise chart were largely based on the 713 water temperature reports sent in by 113 vessels. No derelicts were reported during the second cruise, but a log was reported from on the Banks and two buoys and two alleged floating mines were reported from the waters south of the Banks area.

THE THIRD CRUISE, "MOJAVE," APRIL 21 TO MAY 6, 1928

The *Mojave* at 8 a. m., on April 21, 1928, reached the *Modoc's* position in approximately 43° 00′ N., 52° 00′ W. There the ice observation party and the patrol records were received on board with some little difficulty, due to the heavy swell that was running.

As soon as the patrol was relieved the *Mojave* set a course of 90° true to relocate the southernmost berg last seen by the *Modoc* in 43° 16′ N., 49° 14′ W. Visibility remained good on the 22d, so the search was continued on that date during the hours of daylight. The berg was not found south or southeast of the Tail, nor was any other ice sighted there.

Reports of ice coming in from shipping slackened noticeably during the first part of the third cruise. On the 22d one of the four ice reports received was that of a long low berg in 43° 09′ N., 49° 17′ W. This was suspected of being the *Modoc's* berg of the 19th. It was headed for on the morning of the 23d and reached at 9.30 a. m., being sighted by the lookout aloft when it was about 15 miles off and nearly dead ahead. It was recognized positively as the berg especially being searched for. It had changed but slightly in appearance in the four days since it was left by the *Modoc*.

The berg was used as a point of aim during general quarters and then the remainder of the day was spent searching in the waters of the Labrador current to the northwest up to the Bank and back. No ice was found, though a strong southerly set was encountered with surface water temperatures well below 32°. The southernmost berg was drifted by during the night of the 23d. On the 24th an all-day search to the north and northeast and return revealed no ice.

Evidently the berg being watched was a large solitary one located well to the south of its fellows. Its drift was very interesting. It seemed first to slow down and then to speed up again in a southerly course. It stopped in its career on the 25th and worked slowly to the northwest, then to the west at the rapid rate of 0.75 knot, only to slow up for a couple of days when it had reached a position just south of the Tail.

On the 25th it was foggy part of the time. Three stations were taken at strategic points about the berg that at noon was in 42° 47′ N., 49° 22′ W. At one time during the day a start was made for the French fishing vessel *Madiana* reported by a passing freighter, the *West Zeda*, as 400 miles to the eastward with two seriously injured men on board, both with broken bones. The master of the *West Zeda* was advised by radio what to do until a doctor arrived. The *Tuscania* eastbound, was near the *Madiana*. When it was learned that she had turned about to the westward and would give medical aid very soon, the *Mojave* stopped and resumed station work. This was the second case, during the third ice patrol cruise, where medical advice was furnished by radio to ships without doctors. On the 21st treatment had been prescribed for the chief officer of the *Vogtland* who was suffering from a leg badly hurt by a boarding sea.

The 26th was smooth and sunny but foggy. It cleared up around noon and a search was started for the southernmost berg, but no ice was found until noon on the 27th. Then the berg was relocated in 42° 49′ N., 50° 10′ W., 36 miles west of where it had been seen 48 hours earlier.

The 28th was a beautiful, smooth, clear day because a high pressure area with shallow gradients was over the Banks region. The berg was drifted by all day. Boats were sent out for drill and recreation, as had been done on the previous afternoon. Very little change in the size of the berg could be noticed in the nine days during which it had been under observation. The water it was in was well below the freezing point at all intermediate levels and just a little above freezing at the surface.

At 8.30 a. m. on the 28th a liner was seen racing along to the west hull down to the southward. Her name could not be ascertained. This vessel crossed the patrol area without sending in any water temperature or weather reports. Being far north of the prescribed tracks, she was evidently keeping her radio silent in order to avoid detection. At 3.30 p. m. another vessel, also westbound, passed about a mile and a half to the south of the patrol vessel and the berg. There was no danger to these passenger vessels on the bright smooth day they had, but if they had been beset by fog or darkness a very slight error in their reckoning or that of the patrol vessel standing

by the berg would have sufficed to have put them within striking distance of the southernmost known berg.

On Sunday, April 29, the berg was left early in the morning in 42° 46′ N., 50° 32′ W., in order to take oceanographic stations down to the warm water. Fog shutting in at 2 p. m. forced the abandonment of this plan. The berg left was headed for after the fourth station had been completed, but it was not relocated on account of the bad visibility. The ice patrol vessel was forced to drift blindly four and one-half days, until 4.30 a. m. on May 4, when the clearing conditions permitted the search for the southernmost berg to be resumed.

During these foggy days it was necessary to steam slowly at times to retain position near the most probable location of the berg. Soundings and radio bearings showed the drift was to leeward up over the edge of the Bank, sometimes to the northeast and sometimes to the northwest, depending on the tack on which the vessel was allowed to drift.

During the period from the morning of April 29 until the afternoon of May 5, observations of the stars and sun were possible once only, for a few hours on the morning of May 1. The ship's position was fixed wholly by means of radio bearings and fathometer soundings at all other times. The latter instrument was invaluable as an aid to navigation. The uneven bottom enabled practically as good a track of the ship's position to be kept as though sights were obtainable.

Fifteen oceanographic stations were taken during the cruise. Considerable trouble was had with the salinity testing cabinet, but it was possible to keep it repaired sufficiently to work, and the stations were all calculated on board. The currents found by computation agreed well with what was to be expected from experience in the area. On account of the prevalence of fog and of the necessity for keeping close watch on the southernmost berg, no comprehensive plan of oceanographic surveying could be carried out. The stations had to be taken here and there as opportunity offered.

The only field ice reported during the third cruise was located along the south Newfoundland coast and in the Gulf of St. Lawrence by the Canadian ice patrol vessel *Montcalm*. Seventy reports of bergs and growlers were received from 43 different ships and shore stations. With the exception of the one berg which the patrol guarded the entire cruise near the Tail, and one berg reported on the 23d as in 47° 00′ N., 40° 57′ W., most of the glacial ice was concentrated close to the line from 47° 30′ N., 46° 00′ W. to 44° 30′ N., 49° 00′ W. It probably was disintegrating slowly on account of being in cold smooth water. The weather was remarkable for the slight seas and absence of gales.

It was marred only by summer-time fog caused by southwest winds flowing from the "high" over the ocean around to the north and northeast over the cold waters about the Banks. During the foggy times the sky was nearly always clear and blue overhead.

Besides the routine broadcasts and reports to Washington special ice information was sent on request to 17 vessels. On the 2d of May her water temperature reports showed a large liner to be running in a fog at 22½ knots toward an area where the southernmost berg might be. She was warned and two extra broadcasts were sent out during the day that advised vessels westbound on B tracks to proceed with caution between the fiftieth and fifty-second meridians. These special warnings were sent out at noon and at 4 p. m. as long as the fog lasted. No derelicts were sighted or reported during the cruise. Three spars and five drifting buoys were reported as in or near the patrol area. One hundred and eighty-four vessels cooperated with the patrol by sending in 1,077 reports of sea surface temperatures.

On May 4 the weather was drizzling with visibility of about 4 miles. Search was resumed for the southernmost berg to the northwest along the 100 fathom curve of the Banks. Forty miles had been covered in this direction when a large berg was reported in approximately 43° 02′ N., 50° 40′ W. This point was headed for and reached but no berg was found, although a rectangular search was kept up until dark. The vessel that reported the berg (the *Artigas*) stated that she had not had observations for three days, and that her reckoning might be far out.

On the morning of the 5th the search was resumed around the Tail. Visibility was but little better than on the preceding day with the added handicaps of strong breezes to gales and a rough sea from the west, so at a little after 8 a. m. it was decided to run on a westerly course for the *Modoc*, then 180 miles away in 43° 00′ N., 54° 00′ W. At 6.40 p. m. visual contact was effected and preparations were made to transfer the observing party and records. The relief of patrol was effected successfully early in the morning on May 6 in approximately 42° 25′ N., 52° 00′ W., the conditions of wind and sea having been deemed too severe on the preceding evening to warrant the use of small boats except in an emergency.

THE FOURTH CRUISE, "MODOC," MAY 6 TO MAY 21, 1928

As soon as the *Modoc* took up the ice patrol duty on May 6, the search for the southernmost ice was resumed. Visibility was good, but the day was blustery and on some of the courses the ship rolled deeply to the westerly sea and swell. The Bank just west of the Tail was reached shortly after noon. A rectangular search revealed no trace of the berg reported there on the 4th. At about 6 p. m. there

was received a report of a berg 40 miles to the southeastward in 42° 27′ N., 50° 02′ W. This ice was headed for and the distance was run up before the vessel was stopped for the night.

At daylight on the morning of May 7 a low round water-washed berg was sighted near by. Three oceanographic stations were taken in the vicinity of the low berg and of another small one that was located about 18 miles to the northeast. The bergs were both in water warmer than 42° F., so were eroding and diminishing fairly rapidly. They were drifting slowly southward toward the westbound B tracks, now about 40 miles away from them.

On the 8th it was foggy most of the time due to a light southeast wind. During the intervals when the visibility was fair a few runs were made in search of the berg to the northeast of the small round one, but it was not to be found. The southernmost ice, now visibly smaller and looking like a big floating toadstool, was returned to for the night.

May 9th commenced with clear skies and a rising barometer. It was the beginning of a two-day period of good visibility, during which a large area south and southeast of the Tail was searched. Both of the small bergs being stood by were relocated. The southernmost one was found to be in 42° 08′ N., 50° 10′ W. The other had closed up on it, being only eight miles off.

These bergs were left early on the 9th. A course was laid for a berg reported in 42° 37′ N., 48° 51′W., which was seen by the patrol vessel when 22 miles away. It proved to be an immense piece of ice with pinnacles and ridges sticking up over 150 feet above the surface. With its large natural arch, and its patches of black dirt imbedded in some of the sheer walls it was a striking object in the bright sunlight. All hands gazed at it in fascination as it was circled, while the photographers on board snapped shutters with all their might.

Twenty-four reports of ice were received during the 9th. One of these listed 12 bergs about 60 miles, 70° true from St. Johns, Newfoundland. Only three bergs were reported south of the forty-sixth parallel. A westerly course was run from the arched berg for 30 miles, but no more ice was located by the *Modoc*.

On the 10th the visibility was still good. No less than 37 different messages reporting ice were received, the record for one day so far for the season. Courses were run first to the northeast, then to the northwest up to the 50-fathom curve of the Banks. This was followed to the southwest around the Tail, and then, late in the afternoon, the two small southernmost bergs were headed for.

While over the shoal water several trials were made to get bottom samples for Dr. P. D. Trask of La Jolla, Calif. His apparatus, being designed particularly for muds, failed to work on account of the sandy nature of the deposits.

Luckily both of the small bergs that were left on the 9th were found before darkness and fog closed in. They had diminished greatly during the past two days. The southernmost one was in 41° 55′ N., 50° 00′ W., and was small enough to be visibly rolling to the swell. It was believed that these bergs could not last over three days more under the existing conditions.

The 11th, 12th, 13th, and 14th were days of dense fog. The ship lay drifting in the southerly airs and breezes, forced to await better visibility before attempting to relocate the southernmost ice, or to do any extensive station work. As soon as the fog blanket settled over the cold water the reports of bergs dropped to only one or two a day. These came from the ice-infested areas north of the forty-seventh parallel. The reporting ships on the northern tracks must have been close to disaster to have obtained them. Only extreme slow speed and cautious groping, such as is not practiced generally along the less thickly ice-strewn United States-Europe tracks, could have prevented accidents along these northern lanes.

On the 12th six vessels requested special information. One of these, the Greek steamer *Cape Corso*, whose master was evidently a stranger to the fogs of the ice area, requested aid and advice no less than ten times during the day.

On the 12th, also, hundreds of small whales, probably blackfish, played in thickly grouped schools about the ship. The largest were between 25 and 30 feet long. Tiny ones were seen swimming close to the side of some of the larger ones, probably their mothers. The animals played about the ship aimlessly with slow and powerful motions for hours. There was much puffing and blowing to be heard from different directions as the groups came to the surface from time to time to breathe. Sometimes one or two would raise their heads straight up out of the water and keep them there for a moment, looking like slimy black creosoted pilings floating upright.

By the 14th the vessel had been blown by the steady winds some 70 miles against the Labrador Current up to the Tail of the Bank. During the fog the wind seemed to blow with greater force through the rigging aloft than it did down near the water.

On the 14th four oceanographic stations were taken in the shoal water about the Tail. Doctor Trask's bottom sampler was tried again but without success. In spite of the sensitive flapper valves at the top the deposit was too sandy to remain in the open-bottomed cylindrical pipe that projected downward from the central portion of the sinker.

The 15th was overcast, but good visibility prevailed once more. For nearly 15 hours the search was carried on to the southeast past where the large berg with the arch had been last reported. Thence a southerly course was run to a point where the limit of

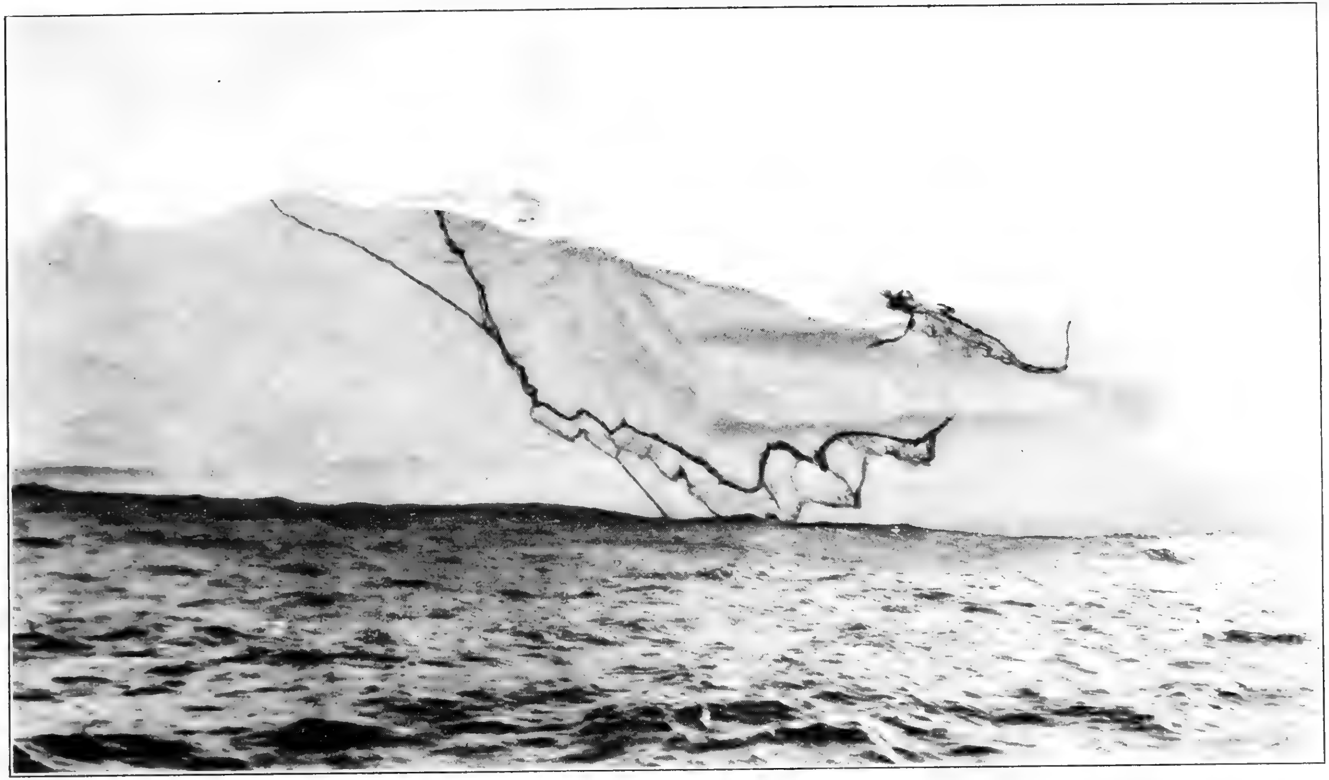

PLATE II.—THIS ICE CLIFF WAS IMPREGNATED WITH DIRT AND STONES. THE MATERIAL WAS PICKED UP BY THE ICE BEFORE IT LEFT GREENLAND AND WAS GRADUALLY DEPOSITED IN THE SEA AS THE ICE MELTED. MAY 9, 1928

PLATE III.—AN ICEBERG IN A LIGHT LOW FOG. THIS ICE WAS VISIBLE FROM THE CROW'S NEST WHEN 3 MILES DISTANT, BUT NOT FROM THE BRIDGE UNTIL LESS THAN 1 MILE AWAY. MAY 31, 1928

visibility toward the south from aloft crossed the limit of visibility toward the north of the vessels westbound on the B tracks. Until dark the search was carried on to the westward roughly parallel to these tracks. Very few reports of ice were received during the day on account of the fog's presistence farther north.

Advantage was taken of the fog, which lasted until 2 p. m. on the 16th, to take two oceanographic stations, one after the other at the same spot, to see how nearly identical the independent measurements of salinity and temperature would be at the different levels. As the results were very much alike, more confidence was felt for the accuracy of the station work done so far.

A sudden shift of the wind from northeast to west occurred around noon. Within two hours this change had cleared up the fog sufficiently to enable a course of 0°, true, to be laid towards the Tail in search for the southernmost ice. No ice was sighted. Intermittent fog hampered the scouting.

The morning of the 17th was ideal for searching, although conditions were favorable for thick weather—a light wind from the southeast with a low barometer. Thirty miles had been run up to the Tail, and thence a considerable distance to the east across the cold water had been covered by 10 a. m., before the fog shut in. The vessel stopped for an hour until it lifted. It shut in again very soon, whereupon the vessel was again stopped. A station was taken between 11.15 a. m. and noon.

During the morning a report was received from south of both the eastbound and westbound B tracks of a piece of ice only 1 foot square in 40° 19′ N., 47° 51′ W. This was believed to be the remains of the great arched berg that on the 10th was 140 miles to the north-northwest. No other report was ever received of this berg or of the two small southernmost bergs of the 10th. All of them must have melted unwatched during the fog. It was decided not to search to the southward any more for this ice but to work up the eastern edge of the Banks, searching for new bergs.

Before sunset two large bergs were found in 43° 34′ N., 49° 06′ W., and 43° 38′ N., 48° 56′ W. They were reported around noon by the *Yorck*, which vessel claimed to have had them 20 and 24 miles off when abeam. This great visibility was doubted, but when the patrol vessel approached them from the south they proved easily visible at those distances.

A short run to the Bank was made from the southwesternmost berg of the pair, but no more ice was sighted. A station was taken at dark, just inside the 50-fathom curve, where no water below 0° C. was found at any level.

On the morning of the 18th the search up the eastern edge was renewed. A berg was located at 9 a. m. in 44° 05′ N., 49° 13′ W.

Courses were run a little farther north, then east, and finally south to return to the two tall bergs seen on the preceding day. When fog shut in early in the afternoon it was realized that these bergs could not be relocated, so stations were taken in toward the Bank until 11.30 p. m.

On the morning of the 19th, it still being quite foggy, a row of six stations was run cautiously to the southeast from the shoal water in 43° 33′ N., 49° 32′ W. Arctic water was found extending east only 20 miles from the 100-fathom curve. From that point a mixed water was encountered at all levels. Forty miles southeast of the Banks the sea surface was 46° F.

At about 4 p. m. a course of 270° true was set for the Tail. Visibility was fair because the haze and fog were soon dissipated after the wind backed from Northeast to Northwest around 1 p. m. Neither of the two large bergs that were 30 miles to the north two days previously were sighted.

On the 20th the weather was still overcast and the moderate Northwest gale that commenced shortly after the wind backed on the 19th was still blowing. Search courses were run to the north and then to the west, but no ice was seen. The night was spent running slowly from the vicinity of the Tail toward the *Mojave*. That vessel was met and the relief of the patrol was effected at 9 a. m. on May 21 in 43° 00′ N., 51° 00′ W.

During the fourth cruise, 27 oceanographic stations were taken. It was found that water below 0° C. was limited in amount, being confined about the Tail to the lower levels of a narrow band. This would seem to indicate a small supply from the north. The weather was moderate but foggy. The only time that the wind attained gale force was during the storm of the 19th and 20th. Visibility of less than 2 miles was experienced during 153 hours, nearly 43 per cent of the time.

Altogether 137 ice reports were received from ship and shore stations. Six logs and minor items of wreckage were reported by steamers from south of the forty-third parallel. Three similar drifting objects were reported from farther north.

One hundred and sixty three vessels cooperated by sending in 1,153 water temperature reports. During the cruise 23 vessels were furnished special ice information on request.

Only eight different bergs were sighted or reported during the cruise south of 45° 30′ N. Those that reached the latitude of the Tail showed a tendency to drift south without curving either to the east or west. One of these, before entirely disentegrating, reached the low latitude of 40° 19′ N., in the longitude of 47° 51′ W.

Prolonged periods of fog kept the patrol vessel from following closely the final drifts of the three bergs that were seen south of the

forty third parallel. Shipping should be made to realize continually the inability of the patrol to keep in close contact with bergs during fog. This greatly increases danger along the tracks during thick periods of weather over and near the Banks.

Fully 75 bergs were reported east and northeast of St. Johns, Newfoundland, during the cruise. Almost all of these were expected to ground or to disintregrate north of the forty seventh parallel. A few would get south in the narrow stream of cold water flowing down along the eastern edge of the Banks. Dynamic computations, which checked well with recorded berg drifts, showed that in the swiftest part this stream was setting south over 24 miles per day.

Extreme southeasterly drift of bergs noted early in the season had stopped. This was accounted for by the marked extension north and northeast of the 60° and the 54° isotherms in the eastern half of the ice-patrol area. The effect of seasonal solar warming was noticeable in all the surface temperature reports that were received.

THE FIFTH CRUISE, "MOJAVE," MAY 21 TO JUNE 5, 1928

The annual surfboat race between the two ice-patrol cutters was held on the morning of May 21 in 43° N., 51° W., as soon as the *Mojave* had received the ice observation party. When the race was over the *Mojave* hoisted her defeated boat and crew and headed east on the lookout for bergs.

Visibility was better than for seversl days and the search revealed the southernmost known bergs to be in 42° 45′ N., 49° 55′ W., and 42° 42′ N., 50° 25′ W. They were last seen by the *Modoc* on the 17th and had traveled about 70 miles to the southwest in four days.

At daylight on May 22 a search was begun up the eastern edge of the Banks from these bergs. Fog was soon run into, so the course was reversed. The fog was outdistanced and, although it remained in sight to the north all day, except for a few wisps it did not again trouble the patrol vessel.

An unknown berg which was reported as in 42° 25′ N., 49° 38′ W., was run for, found, and examined. It was a small one of the drydock type with three distinct peaks separated by water. The sea was so smooth that this berg was examined closely from a boat. Photographs were taken of it with the *Mojave* in the background. It was not expected to last long because it was in 44° water and was crackling almost incessantly as if its ice was under great tension and stress.

The 23d was a day of glassy seas and calms. Unfortunately, it was foggy most of the time. When visibility permitted search courses were run for the solid berg seen the preceding day. It was found about 1.45 p. m. After circling it a search course was started to the west. Shortly afterwards the fog closed in thick. It was determined to

run to a point about 3 miles east of the berg before stopping to drift for the night. A course was set that it was thought would lead well clear of the ice, but soon a white radiance was seen in the fog ahead a little on the opposite bow to the one on which the berg was supposed to be. Collision with the ice was avoided by yards only by the giving of full left rudder.

On the 24th the fog continued, so no ice was seen. Better visibility prevailed further north and numerous berg reports were received from vessels on the Canadian tracks east of St. Johns. Two stations were taken during the day to try out the oceanographic equipment. It was found that although the surface water in 42° 37′ N., 51° 02′ W., was warmed to 37° F. by the sun, the water at the 50 and the 125 meter levels was about 31° F.—pure berg-bearing arctic discharge.

As there had been little wind during the foggy weather a couple of hours' run to windward with the fair visibility of the morning of the 25th sufficed to relocate the large, solid berg. Sights placed it in 42° 10′ N., 50° 46′ W., still moving southwest about 18 miles per day.

A search to the west and south failed to reveal the berg that had been in that direction from the big berg a few days previously. Sixty-two-degree water was encountered, so it was considered likely that this berg had entered the warm water and entirely disintegrated. The solid, large berg was returned to for the night.

On the 26th foggy conditions prevailed over all the cold water regions. Only two bergs were reported and none were sighted. Two oceanographic stations were taken. The next day a search was carried on for the near-by solid berg when visibility permitted. It was reported by a steamer as in 42° 04′ N., 49° 28′ W., n the afternoon. This spot was run for at 110 turns, but fog came on that forced the patrol vessel to stop before the berg was found. While taking a station at 6 p. m. a Greene-Bigelow water bottle and two reversing thermometers were lost overboard due to their being clamped too loosely to the sounding wire.

On the 28th a cold north-northeast wind reversed the recent weather conditions, giving good visibility over the cold water and fog and vapor over the Gulf Stream. A northerly course was accordingly run into clear weather where sights were obtained. These showed the vessel to be 40 miles south of her reckoning. The solid berg was found at 3.30 p. m. It had drifted in a general east-southeast direction at 1 knot for the past three days. The area of the top was smaller but the berg was still quite solid and high. There was water-line evidence of its having tipped recently due to uneven melting below water. No other bergs were found during the day.

The 29th was foggy and practically calm. A few minutes of fair visibility permitted the obtaining of sights that showed the rapid southerly drift was being continued.

On May 30th the visibility was good until 5 p. m. Just before that time, thanks to a report from a passing steamer, the berg of the 17th was found in 41° 10′ N., 48° 17′ W. It was drifting southeast 36 miles per day and was in a cold finger of arctic water that still had subfrigid temperatures 50 meters below the surface. Only a few miles away to the south was 72° Gulf Stream surface water.

West-southwest winds and fog prevailed over the cold tongue of Labrador water on the morning of May 31. A station was taken at 8 a. m. that was most disastrous. Seven bottles were sent down on the line. They had all been tripped and were being hauled up. As the first bottle approached the working platform the chief electrician's mate operating the winch made a move to stop the motor, but his hand slipped from the operating lever, and, before he could grab hold again to move it to the stop position, the upper water bottle had risen to the fair-lead block on the span near the davit heads. When it struck this block the strain immediately became so great that the wire parted and 7 Greene-Bigelow bottles, 14 reversing thermometers, 2,400 feet of $\frac{5}{32}$-inch wire rope, one 300-pound weight, and 7 "messengers" were lost. As all of the *Mojave's* best equipment was on the wire, station work was much hampered until the arrival of the *Modoc* on patrol.

It was noted that vessels but 20 miles to the south were enjoying fine clear weather, so a course of 200° true was laid for the warm water of the Gulf Stream. After running slowly for a few minutes a large growler was sighted in the fog. A little farther to windward the main berg of the 17th was found. It was seen from aloft over the low fog when 3 miles off. From the bridge it could not be seen when only 1 mile distant.

This berg was positively identified as the same one that had been trailed so long. It had rolled until its characteristically curved top now formed a perpendicular side. It looked while being approached like a great white submarine with a central cunning tower and sloping tapered ends. Clouds of vapor were being rolled from the ice by the warm wind. About 5 miles south of the berg there was no fog. There the patrol vessel drifted all afternoon, keeping watch on the berg that could be dimly seen until 6 p. m. through the mists that continued to hang low over the cold water.

Good sights taken during this time showed that the berg had drifted no less than 54 miles on a course of 80° true during the past 24 hours. As was the custom during foggy weather recently, special broadcasts were sent out every hour that gave the changing positions of the southernmost known ice, and warned vessels on the B tracks to proceed cautiously on the lookout for unknown bergs that might be coming down from the north unseen in the fog.

For over a month the extreme southerly drift of ice had necessitated the presence of the patrol in the south and had precluded the proper searching of the eastern edge of the Banks for new bergs. The few reporting vessels that had crossed the area between the Canadian tracks and the B tracks were much hampered by fog. The location and number of bergs now south of the forty-eighth parallel and between the fiftieth and the forty-seventh meridians was much in doubt. It was believed likely that many more than the eight reported and sighted since May 25 existed in this area.

On the 1st of June the patrol vessel was still south of the edge of the fog area, but the berg could not be seen. Sights taken during the morning showed the phenomenal drift of 63 miles in 19 hours. The set was now 20° true. As soon as the heat of the sun burned off the fog over the cold water a bit a search was carried on to the westward. Numerous growlers were found in the vicinity of 42° 02′ N., 46° 22′ W. These were thought to be the remnants of the berg of the 17th.

Search to the west and southwest for larger parts of the berg proved futile on account of the fog. The ice seen was in 60° water and would hardly last over night. Around 5 p. m. the growlers were returned to. They were much smaller already. A course of 225° true was run for 5 miles. Then the main berg from which the smaller pieces had been blown to leeward was found in the fog. It was low and very much cut into by the warm water, but it still possessed much mass. No resemblance to the berg being followed could be found, but it must have been that one on account of its location.

On the morning of June 2 north winds were blowing and the clear weather following a shallow "low" was enjoyed. A 20-mile run towards the west sufficed to reach the berg again. It was drifted by all day. Once around 1 p. m. the berg suddenly listed 90° when a large piece of ice broke off. In the afternoon water temperatures were taken all around the berg, some of them close to it from a boat. Sixty-degree water was found at all times. Several persons went in swimming among the growlers surrounding the berg from one of the ship's boats.

By dark the berg had become reduced to small proportions. Its highest pinnacle was about 40 feet above the water and it was about 90 feet long by 80 feet wide. Its position at 8 p. m. in 43° 00′ N., 46° 17′ W. showed that it had recurved and was now drifting away from the steamer lanes. It would certainly melt enough to cease to be a serious menace to navigation within 36 hours. Accordingly it was left. A course was run during the night to the northwest so as to arrive at a position in the cold current off the eastern edge of the Banks early on the morning of June 3.

The berg left had been trailed with great difficulty through fogs and mists for 16 days along a curving track more than 480 sea miles

long. This track was very interesting for it showed clearly the distribution of the Labrador water south of the Tail of the Banks. It is worthy to note that at the same time that the trailed berg was drifting north-northeast along a cold tongue of water, another berg was known from frequent reports to be drifting south-southwest at almost the same speed on the western edge of another cold tongue from the north. On June 2 the latter berg was reported in the very low position of 39° 39′ N., 50° 00′ W., apparently drifting south-southwest at 2½ knots. The next day it was last reported as at 38° 59′ N., 48° 51′ W., the southernmost ice reported or sighted during 1928.

Good visibility prevailed on June 3 until 5 p. m. The cold stream was thoroughly searched between 45° 15′ N. and 44° 00′ N., but no ice was located. The warming influence of Gulf Stream mixing was noted inshore to the 100-fathom curve. Water less than 40° F. in temperature was found on the surface only in a very narrow band that was crowded over onto the Banks. On this account it was believed that very few more bergs would be able to drift below the forty-fifth parallel this season.

June 4 was spent running slowly down the eastern edge of the Banks working toward a rendezvous with the *Modoc*. The fog was so dense at times that it was necessary to stop the ship.

During the fifth cruise no gales whatever were encountered. There was fog 50 per cent of the time. When it is considered that several days were spent in warm water south of the fog area and that on at least two days a knowledge of surrounding conditions enabled the patrol to dodge the fog, an idea of the difficulty of keeping in touch with the bergs in cold water during May and June can be appreciated. The patrol felt keenly the probability of the existence of unreported bergs south of the forty-third parallel, and continually warned shipping in the regular broadcasts to beware of unknown bergs. It was made routine to send out such warnings with the location of the southernmost known dangers every hour during fog and darkness.

Only six different bergs were sighted and reported south of 45° 30′ N. during the period from May 21 to June 5. It seemed as though most of these few bergs that succeeded in passing down through the narrow neck of cold water along the eastern edge of the Banks made a grand circuit counterclockwise around the edges of the cold mixed waters southeast of the Tail of the Banks. Some of these bergs tended to follow the edges of the cold tongues of water that extended from the large cold body. A conclusion to be drawn from a study of the tracks and distribution of this ice is that while bergs may be met in warm water, a cold tongue often forms a broad avenue along the edge of which bergs can readily drift along at from 2 to 3 knots.

The finding of water of 60° F. in temperature about the berg on June 2 from 2 miles away right up to within from 100 to 50 feet of it in all directions shows what little dependence can be placed upon a fall of temperature to give warning of proximity to bergs.

The smoothness of the sea during the fifth cruise prevented any very rapid disintegration of the ice seen. A steady slow dissolving was the rule. This was speeded up somewhat by calving and the consequent listing about in the warm water.

No field ice was reported during the fifth cruise. Sixty different bergs were reported by vessels from the Cape Race tracks. Only one of these was located east of the forty-ninth meridian. A tendency for the ice to drift through the Gulley and to the west past Cape Race was noted. Only a very few of the easternmost of the northern bergs were located so they could possibly get south of the Tail. It was not believed that any of them would get so far south.

The disintegration of the northern ice could not be observed as the patrol vessel was kept in the lower patrol latitudes by the few bergs south of 43° N. The continuance of solar warming in the north was noted from the reporting vessels' water temperature reports; 34° surface water had disappeared from the map. All the bergs south of 48° were undoubtedly being eaten into about the water line and calving and disintegrating at an increasing rate.

Ten oceanographic stations were taken and computed. A little more would have been accomplished except for the loss of the equipment on May 31 described above. The salinometer on board was in need of a thorough overhaul. In addition to having to be heated by makeshift methods after the burning out of the heating coils its water bath sprang a leak during the cruise and had to be taken down and resoldered.

In all 119 ice reports were received from ships and shore stations. Special ice information was furnished to 18 vessels. No derelicts were reported, but no less than 15 reports of minor items, such as logs and buoys, were received from passing ships.

Good visibility attended the final run to the westward past the Tail on the night of June 4. On the following morning at 9 o'clock the *Modoc* was met in 43° N., 53° W., and there the oceanographic party was transferred and the relief of patrol was effected.

THE SIXTH CRUISE, "MODOC," JUNE 5 TO 20, 1928

Good visibility with moderate weather conditions prevailed when the *Modoc* took over the ice-patrol duties from the *Mojave* on June 5. The day was spent running to the eastward toward the Tail. Water warmed to over 45° F. was noted all the way from 43° N., 53° W., to 43° N., 50° 15′ W. To the east of that 40° surface water from the north was encountered.

Numerous bergs were reported from the Cape Race tracks and three bergs from southeast of the Tail. The southernmost of these consisted of a pair of large bergs reported to be in 41° 25′ N., 48° 31′ W. This position was directly on the B tracks, so the *Modoc* steamed all night toward it.

The 6th and 7th were overcast and mostly calm, but the excellent visibility continued. A thorough search in which vessels on the B tracks assisted was conducted, but the two bergs could not be found. As the water was comparatively warm (from 45° F. to 66° F.) it was concluded that they had entirely melted. Two small bergs seen on the horizon by the reporting vessel on June 5 had probably been mistaken for and reported as large bergs as is often done.

The whole of daylight on June 8 was spent running back to the northeast to the Tail. It was hoped that the good visibility would continue and that the Labrador current along the eastern edge of the Banks could be searched for ice. From June 2 to 7 eight bergs had been reported along the northern end of this edge. They were no doubt moving south, some of them but how far they had moved it was impossible to tell on account of the scarcity of reporting vessels crossing the ocean between the Canada-Europe and the United States-Europe tracks.

June 9, 10, and 11 were overcast foggy days. At times the visibility was good enough to permit search courses to be run, but not much progress was made. Just about enough distance was covered to enable the scouting to stem the cold current flowing southwest past the Tail between the forty-ninth and fiftieth meridians. This current was found by the stations taken and by the actual drifts experienced to be setting to the south and the southwest about 24 miles per day. Radio bearings from Cape Race and the fathometer depths enabled pretty close check to be kept on the ship's position, even though it was possible to obtain but two sights in three days. The Labrador current was about 40° on the surface, but temperatures below 32° F. were found around the 50-meter level at two of the stations taken east of the Tail during this time.

On the 11th a 3-pinnacled berg with water separating the sections was sighted. Although the day was overcast and dull this berg was seen by the lookout aloft when 20 miles distant. It was in 43° 04′ N., 49° 00′ W. at noon. Plans to scout up to the north from it had to be abandoned when rain and fog came on. Early in the afternoon the patrol vessel returned to the berg and took two stations in its vicinity. When these were worked out they showed that the berg was drifting south or southwest and not northeast as might have been thought from its rather far offshore location.

At 2 p. m. a boat was lowered to allow the two newspaper men on board to examine a berg from close quarters. They had a great

opportunity to observe action, for when they were near it one of the three pinnacles broke from the main berg where it had been eaten into about the water line. Hundreds of tons of ice fell off into the sea with loud reports and roars. The berg did not capsize but rose up and acquired a permanent tilt of about 30° when it was relieved of the weight of one end.

A considerable amount of ice in small pieces was picked up by the boat and brought aboard. It was hard and brittle with a tendency to crack up into pieces with very irregular surfaces if struck hard or dropped. The ice itself was very clear but it contained many of the usual air bubbles, each about half the size of small common pinheads.

At 8 a. m. on June 12 while the *Modoc* was drifting in a dense fog in the vicinity of the berg sighted the previous day a report was received from the *Tampa,* a freighter, stating that they had just passed a dory with two men in it apparently lost in the fog. They were endeavoring to relocate this boat. The patrol ship immediately started for the position, about 80 miles to the northwest, to assist in the search. Before half the distance had been run the *Tampa* radioed that the weather was now clear and that no dory was in sight but that a large sailing vessel was near by. As they assumed this to be the mother ship of the dory they had resumed their course to the east. The *Modoc* was stopped to drift again in the fog.

Very soon the clear weather reached the *Modoc.* It was decided to run up the Labrador current until dark, searching for ice coming down. A strong current from the north with pronounced tide rips was observed over the uneven bottom east of the 100-fathom curve between the parallels of 43° 30′ and 44° 00′ N. The *Tampa* and the *Gripsholm* ran across the Labrador current to the north of the forty-fourth parallel. Neither they nor the patrol vessel sighted any ice on June 12.

On the 13th the patrol vessel steamed to the southwestward and finished searching the lower end of the Labrador current. When no ice was found it was felt pretty certain that the only berg south of 44° 30′ N. was the one found on the 11th near 43° N., 49° W. It was not seen near its previous location on the 13th because it had probably drifted to the southwest past the Tail by that time.

On the 14th, 15th, and 16th it was foggy or thick and stormy practically all of the time so no searching could be carried on. On the 17th the weather cleared. It was thought that the berg of the 11th had melted by this time. At any rate it was futile to waste valuable time trying to find this single small isolated berg after such a long separation. It was deemed more advantageous to search up the Labrador current as long as the visibility held good. Such a course was followed but no bergs were sighted in the area east and

northeast of the Tail on the afternoon of the 17th although a double lookout was posted aloft and much area was covered.

From the 13th to the 19th several weather reports by radio were sent each day to Cape Race for the benefit of the two planes waiting in Newfoundland for favorable conditions to cross the ocean. These reports gave not only the weather of the patrol vessel but also contained a compilation of late reports from a number of vessels strategically scattered over the ice-patrol area. Messages from the plane *Friendship* to Cape Race were intercepted on the afternoon of June 17 until about three hours after the plane had left Newfoundland for Europe.

Advantage was taken of continued good visibility on June 18 to search about 4,000 square miles of the Labrador current between 43° 20′ N. and 45° 30′ N. No ice was seen. Unfortunately five hours of dense fog on the following day prevented the search from being continued as far north as had been planned. By running at 80 to 85 revolutions per minute an area of about 3,500 square miles was searched on the 19th, however. This area lay between 45° 10′ N. and 46° 40′ N. and just west of the forty-eighth meridian. Again no ice was seen.

The *Modoc* spent the night of June 19 steaming across the Banks toward a rendezvous with the *Mojave*. That vessel was met and given the patrol duty at 11 a. m. on June 20 in approximately 45° 08′ N., 51° 39′ W.

No derelicts were seen, but one was twice reported during the sixth cruise. It was a schooner floating bottom up and was last reported on June 16 from 46° 31′ N., 55° 25′ W. Ten buoys, trees, and logs were reported to the patrol from in and near the ice-patrol area.

During the sixth cruise 15 oceanographic stations were taken, bringing the total for the season up to 95. During 122 hours, or 34 per cent of the time, visibility was less than two miles. Very moderate weather was experienced. It was only during the blow of the 15th and 16th that winds as strong as force 7 were observed. The wind blew with greater force than 5 during but 34 hours.

Continued surface warming of the sea was noted—38° water retreated north of the forty-eighth parallel during the sixth cruise as completely as 34° water retreated north of the same latitude during the fifth cruise. This effect undoubtedly made the ice disintegrate faster and faster in the higher latitudes. Only one berg was seen during the whole cruise and that one but for a short time on one day, so no great amount of first-hand information regarding disintegration could be accumulated.

The isotherms on the cruise chart are based on 1,147 observations from 131 vessels; 87 reports of ice were received during the 15-day cruise from 36 ship and shore stations, but during the last week the falling off was so great that only 16 ice reports were received

from 10 stations; 31 ships were furnished with special advice on request.

At the end of the cruise on June 20 it was estimated that about 27 bergs remained south of the forty-eighth parallel. Fully 22 of these were grounded on, or were very near to the Newfoundland coast and would never get anywhere near the United States-Europe tracks. The three bergs reported and the one sighted south of the Tail all undoubtedly melted before the cruise ended.

On June 20 it could be stated fairly definitely that there was no ice nearer the B tracks than 250 miles. To reach these tracks it would have to follow the Labrador current down along the eastern edge of the Banks and past the Tail, a distance of over 350 miles. At this season the time that would be consumed in traveling this distance should suffice to melt any ordinary berg that might hereafter have a tendency to drift south because of its favorable location in the axis of the Labrador Stream. The ice menace to the B tracks was believed definitely over for the season of 1928. The above conclusion was arrived at in a conference held on board the *Modoc* as soon as the *Mojave* was met on the morning of June 20.

THE SEVENTH CRUISE, "MOJAVE," JUNE 20 TO 23, 1928

The *Mojave* took over the oceanographic party and the ice-patrol duty at about 11 a. m. on June 20 in 45° 09′ N., 51° 40′ W. Nearly all the oceanographic gear on the *Modoc* was received at this time also, for further transfer to the *Marion* for use on a proposed cruise to Greenland waters.

Just after the relief was effected the commander, international ice patrol, sent a message to Coast Guard headquarters from the *Modoc* recommending the discontinuance of the 1928 patrol. Pending receipt of orders resulting from this message the *Mojave* undertook to search again along the eastern edge of the Grand Banks from 46° 45′ N. to 43° N.

By running at 100 revolutions per minute during all times of good visibility the second search within a week of this area was finished before dark on June 22. The limiting longitudes were 47° 00′ W. and 51° 30′ W. Again no ice was seen, but a band of water about 30 miles wide with surface temperatures from 39° to 41° F. was encountered until the patrol vessel had passed to the westward of the fifty-first meridian. Moderate weather prevailed and the only thing that hampered searching was the usual fog that was occasionally experienced in banks and patches.

At 6 p. m. on the 22d orders were received by radio from the *Modoc* at Halifax for the *Mojave* to discontinue the ice patrol and to return to Boston. Favored by easterly breezes at first, but hampered greatly

by fog later on, the *Mojave* finally arrived at the Boston Navy Yard on the afternoon of June 26, 1928.

The isotherm chart for the short seventh cruise was based on but 366 temperature observations sent in by 29 cooperating vessels. Only one ice report was received from south of the forty-eighth parallel. This was for a small berg reported in 46° 15′ N., 48° 17′ W. on June 21.

Vessels apparently commenced using the Belle Isle tracks on June 21, for 23 bergs and several growlers were reported to the patrol on that date from between Greenly Island and 52° 30′ N., 53° 00′ W.

Special information on request was sent to three vessels. No derelicts were heard of, and but one spar and one buoy were reported from within the patrol area. No oceanographic stations were taken.

Upon the discontinuance of patrol messages of thanks for efficient assistance were sent to the radio stations at Cape Race, Halifax, and St. Pierre. The final ice broadcasts were sent out on the evening of the 22d and on the morning of the 23d. They contained thanks to all cooperating ships for their indispensable assistance in the form of ice, water temperature, weather, and other reports.

Before leaving the patrol area, the following gratifying message was received from W. F. Berg, master of the *Vacoil*, "Realizing the hardships endured by the patrol, I wish to express my appreciation for your most valuable assistance to us during the past season." Before reaching Boston similar messages of appreciation were received from the *Majestic* and *Olympic*.

RADIO COMMUNICATIONS

In addition to being sister ships structurally the *Modoc* and the *Mojave* were equipped with identical radio apparatus for the ice-patrol work. Each vessel had one T–2 2-kilowatt tube transmitter, using either CW, ICW, or phone transmission; one T–4 200-watt tube transmitter using either CW or ICW, which replaced the 2-kilowatt spark set used during 1927; and a 500-watt XA crystal control high-frequency transmitter. The latter was similar to the one used during 1927 with some improvements and redesigning of the circuits used. The alterations were made by the United States Naval Research Laboratory for the Coast Guard, and served to make the set more efficient and consistent than before.

Direct communication with NAA, the United States naval radio station near Washington, D. C., was more successful than in any previous year. This traffic was all handled on high frequencies and the average distance between the ship and the shore station was approximately 1,350 sea miles.

The receiving apparatus on each ship consisted of a CGR–5 low-frequency receiver used for ship traffic and for communication with shore stations on intermediate and low frequencies. An RG receiver was used for high-frequency work, covering from 1,000 to 20,000 kilocycles. No real trouble was experienced with any of the radio apparatus. Kolster radio compasses were used to assist the vessels to find each other at relieving times. They would have been invaluable, also, had any assistance work been necessary during the season.

A splendid spirit of cooperation was noted on the part of the ship and shore stations in the vicinity of the patrol regions. There was an increase of over 17 per cent in the number of water-temperature and weather reports received from passing vessels over the 1927 season. A regular annual increase in all traffic seems to be the rule. An idea of the present volume can be gained by reading the tabulation on page 38 at the end of the summary report of the commander, international ice patrol.

The following schedule shows the times when regular routine traffic was handled. The times given are all Greenwich mean civil times and show the conditions at the beginning of the season. A few minor changes were made in the schedules with NBD, Bar Harbor, Me., during the progress of the patrol:

Time	Remarks
0000	Radio broadcast to shipping on 175 kilocycles.
0030	Report to Government observer, Washington, giving meteorological information.
0030	To Hydrographic, Washington, giving latest ice news.
0100	Schedule with Bar Harbor, Me.
0300	Receive from NAA, Washington, D. C., traffic on hand for ice patrol and receipt for traffic received via Bar Harbor.
1100	Radio broadcast to shipping on 425 kilocycles.
1200	Radio broadcast to shipping on 175 kilocycles.
1230	Report to Government observer, Washington, giving meteorological information.
1300	Schedule with Bar Harbor, Me.
2300	Radio broadcast to shipping on 425 kilocycles.

SUMMARY REPORT OF THE COMMANDER, INTERNATIONAL ICE PATROL

Commander W. H. Munter

The *Mojave* left Boston on March 20, 1928, to inaugurate international ice patrol. When 43° N., 52° W. was reached on March 24, the first patrol cruise was started. The *Modoc* divided evenly with the *Mojave* six full 15-day cruises. The patrol was discontinued at word received from Coast Guard headquarters on June 22, when the *Mojave* was on the third day of the seventh cruise.

Halifax, N. S., was used as a base for fuel and supplies as in previous seasons. During the season the two patrol vessels cruised a total of 18,083 miles, including the distance run in going to and from the base.

Weather during the whole time was remarkably moderate on the average. A few moderate gales, but no really severe ones, were experienced. Somewhat more than the usual amount of fog prevailed. The season was a very early one. The effect of this, combined with the mild winter preceding, was seen in the practical absence of field ice south of the forty-seventh parallel, in the unusually small amount of field ice reported by the Canadian ice patrol in the Gulf of St. Lawrence, in the general use of the Belle Isle tracks by the early date of June 21, and finally in the early recall of the international ice patrol vessels. The patrol's discontinuance on June 22 was earlier than in any year since 1920, when it ended on June 20.

While the total number of bergs that drifted south of 48° N. was greater than normal, less than half of the normal number of 51 bergs drifted south of the forty-third parallel. Early in the season many of the bergs came south well to the eastward of the Grand Banks and entered the Gulf Stream current south of Flemish Cap. They were then carried toward the northeast and melted clear of the B United States-Europe tracks but foul of the steamers on the C United States-Europe tracks between the forty-third and the forty-seventh meridians. There is grave danger under such conditions in adhering to the C tracks as late as was done this year.

During May the average position of the bergs was farther west in the Labrador current with the result that many of them were caught in the branch that flows along the eastern edge of the Grand Banks; some of these avoided being set onto the Banks or being curved off to the northeast. They are the ones that drifted south past the Tail of the Banks.

Towards the end of the season the bergs came down still farther west and most of them stopped in the slack water over the northern part of the Grand Banks or stranded along the Newfoundland coast between St. Johns and Cape Race. When the patrol was ended even these westerly bergs were thinning out rapidly, due in a large part, no doubt, to disintegration farther north. This would naturally be caused by summer solar warming of the air and sea surface water.

It was noted that a large pool of arctic and mixed water remained south of the Grand Banks right up to June 22. This was fed by a narrow but swift stream running along the eastern edge of the Grand Banks. A large proportion of the bergs that reached the pool via this stream was swung in a counterclockwise direction around it at speeds varying from 15 to 60 nautical miles per day. During the latter part of May and the first part of June six bergs went south of the forty-second parallel in this circulation. One of these on June 3 attained the unusual latitude of 38° 59′ N. in the longitude of 48° 51′ W. It had traveled rapidly across both the eastbound and westbound B United States-Europe tracks, then in effect, by running along one of the tongues of water radiating from the cold pool. Its most southerly position was due east of a point between Baltimore, Md., and Washington, D. C.

Ninety-five oceanographic stations were taken during the season. These were all worked out in accordance with the methods described in Bulletin No. 14, United States Coast Guard. The calculated currents usually agreed closely with the sets and drifts encountered and with the actual observed berg drifts. Because of the necessity for scouting for bergs during intervals of good visibility and also for following menacing bergs for long periods in the vicinity of the steamship lanes, the stations taken were usually just about where and when opportunity allowed. Had the patrol vessel been more free, their distribution in the patrol area would have been much better arranged.

One unusual feature of the bergs sighted this year was the amount of earth deposits in many of them. Some had layers of brownish gray matter streaked through them like icing between the layers of a cake. One was seen that had great irregular lines and patches of what looked like black soil embedded in one of its precipitous sides. It was impossible to obtain any dirt samples from the bergs. It is very difficult and dangerous to board a berg at sea. Only especially favorably shaped ones permit a footing to be obtained and then it is only during time of comparatively smooth sea that such bergs can be approached and landed on from small boats with any degree of safety.

Another unusual matter may prove of interest to ornithologists. Besides all the usual forms of bird life about the bergs and the Banks, this season snowy owls were seen on several of the icebergs. The owls,

if they had been present in former years, were either not observed or not recorded. These birds are native to the arctic regions only and are never seen so far south unless there is a shortage in their usual food supply in their regular haunts. The owls found inhabiting the bergs this season were supplied bountifully with the sea birds common to the regions comprising the Grand Banks.

The most vital thing in making the ice patrol of real value to shipping is radiotelegraphy. Here, as in previous years, the most gratifying cooperation was had from ship and shore stations. The communication personnel and apparatus of the ice patrol again proved equal to the task. Every effort should be continued to keep the radio material of the patrol vessels abreast with the progress of this most beneficial science. The magnitude and importance of the communication work of the patrol can be grasped in part by a study of the following figures:

Number of routine broadcasts transmitted	380
(At the height of the ice season these messages averaged about 300 words each.)	
Number of official messages to Washington	348
Ice and other information given to vessels on request	113
Water temperature and weather reports sent in by vessels	6, 534
Total number of vessels cooperating with the patrol	489
Number of ice and obstruction reports received by radio	644
Number of times medical treatment was given by radio	4
Violations of steamship track agreements reported	2
Total number of words transmitted and received by radio	450, 460

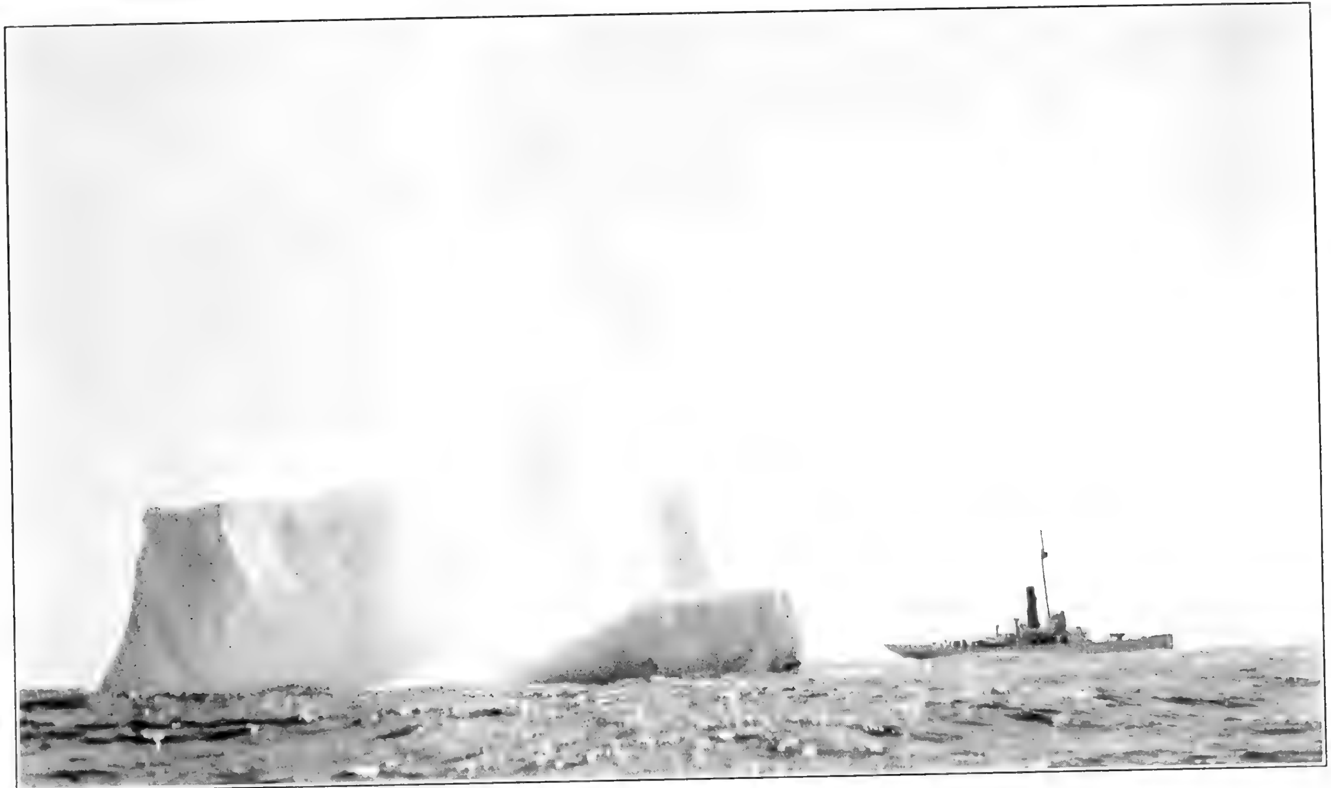

PLATE IV.—THE "MOJAVE" AND AN ICEBERG AS SEEN FROM A SHIP'S BOAT

PLATE V.—ICEBERG SEEN FROM THE "MODOC" MAY 17, 1928. THE TWO HIGH THIN WALLS APPEARED LIKE THE OUTER SIDES OF A FLOATING DRY DOCK

TABLE OF ICE AND OTHER OBSTRUCTIONS, 1928

WEATHER

This section gathers together certain meteorological facts observed on the ice-patrol vessels during the 1928 ice season. The conditions can be taken as those that prevailed at 43° N., 50° W., for all practical purposes, but too great stress should not be placed on this position, for the patrol ships cruised from 46° 50′ N. to 40° 40′ N. and from 53° 00′ W. to 43° 20′ W. There were areas of cold surface water and of warm surface water in the patrol area which had consequent marked effects on local weather, especially with respect to fog and surface air temperatures. It was noted that the air temperatures followed the values of the sea temperatures closely and quickly most of the time wherever the patrol vessels went.

The weather diagrams for each month give at a glance the wind directions and forces averaged for every 12 hours, the barometric curve, and the time and duration of fog and low visibility. This year maximum and minimum and average surface air temperatures are given for each month. The scientific value of these temperatures is mitigated by the above noted mobility of the observing stations and by the fact that ordinary poorly exposed ship's air thermometers were used in making the observations. It is believed that the values will be of interest, however, in showing about what temperatures should be expected and prepared for on ice patrol. The average air temperatures were obtained roughly by adding all the daily maxima to all the daily minima and dividing the sum by twice the number of days.

MARCH

Maximum air temperature, 50° F.
Minimum air temperature, 28° F.
Average air temperature, 37.8° F.
Visibility was less than 4 miles 57 per cent of time.
Visibility was less than 2 miles 34 per cent of time.

The ice patrol was in effect during only the last 10 days of March. The percentage of bad visibility was extremely high for early in the season. There were three days of dense fog from the 25th to the 28th caused by Southwest winds blowing, as in summer, over the cold water. They were apparently caused by the atmospheric circulation set up between a High over the ocean to the south and a Low situated over the northeastern part of North America.

Only two cyclones affected the barometer on the patrol vessel to a marked degree. The one whose center passed just to the south on

the night of March 23 gave a few hours of moderate gales from the Northwest on the 24th. These were the only gales of the month, for the storm of the 31st did not produce anything stronger than a fresh breeze In general the weather was very moderate for March.

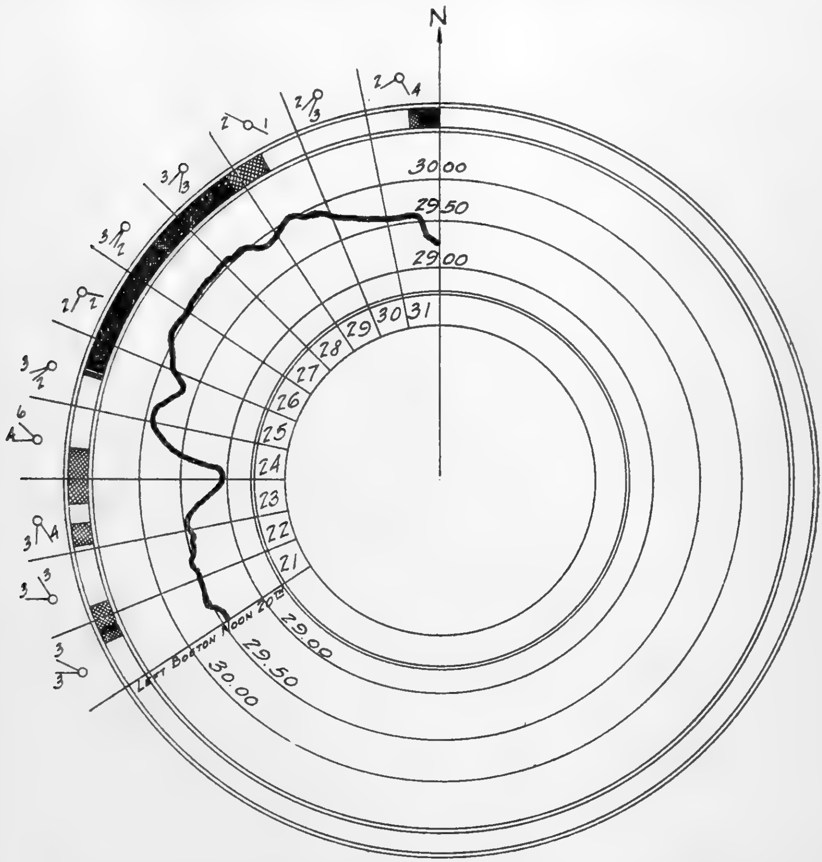

FIGURE 2.—March weather diagram. Inner figures show day of the month; the next band out contains the record of the atmospheric pressure; the next outer one indicates the degree of visibility (black areas are for visibility of less than two miles and cross-hatched areas for visibilities between two and four miles); the outer margin shows the average direction and force of wind per 12-hour periods, midnight to noon, and noon to midnight.

APRIL

Maximum air temperature, 52° F.
Minimum air temperature, 30° F.
Average air temperature, 38.7° F.
Visibility was less than 4 miles 26 per cent of time.
Visibility was less than 2 miles 18 per cent of time.

Fog and poor visibility prevailed during April just about normally; that is, to the average extent that the ice patrol has experienced during the past eight years. There were a number of days of high barometer and fine weather.

The barograph curve records no less than 12 depressions for the month. None, except the one that ushered in the first, were particularly deep where the patrol vessels were. Only three were able to give the ice patrol winds of gale force for as long as 12 hours, being for the most part very brief as well as shallow.

The fully developed cyclones of large area passed to the northeast over Newfoundland and Labrador, well to the north of the Grand

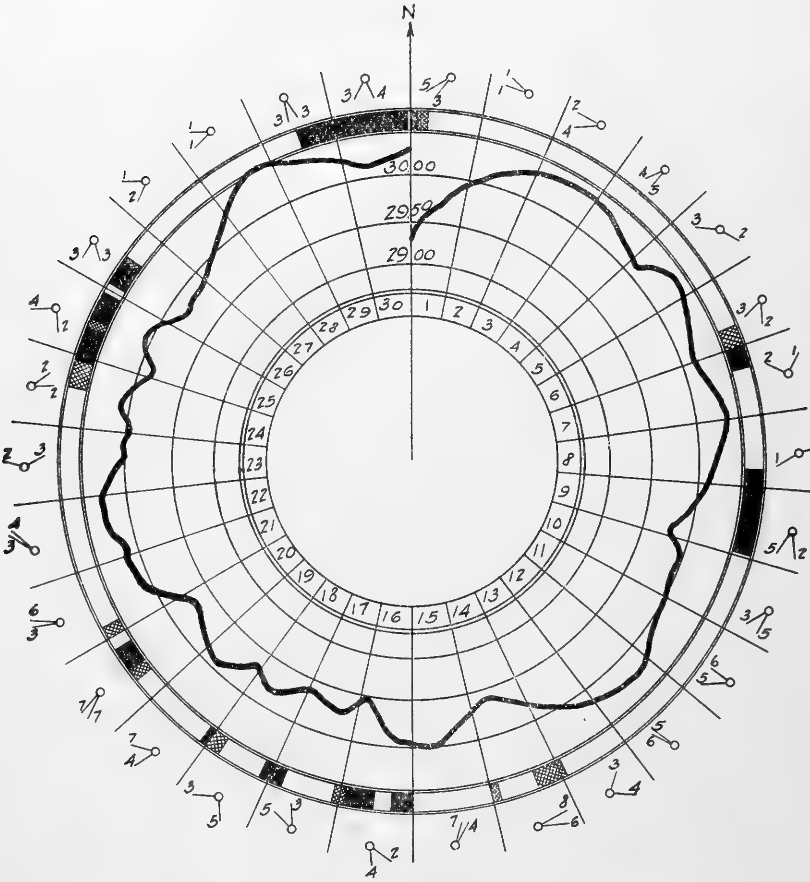

FIGURE 3.—April weather diagram.

Banks. The depressions that went over the patrol vessel were, many of them, secondaries of the larger Lows. Some of these small storms were noted over the States traveling along more or less parallel to the larger ones. Others, it seemed to the patrol, were born between the Grand Banks and the New England coast, as they were either detected by means of ship reports or not detected at all until they unexpectedly broke.

MAY

Maximum air temperature, 65° F.
Minimum air temperature, 36° F.
Average air temperature, 44.8° F.
Visibility was less than 4 miles 55 per cent of time.
Visibility was less than 2 miles 48 per cent of time.

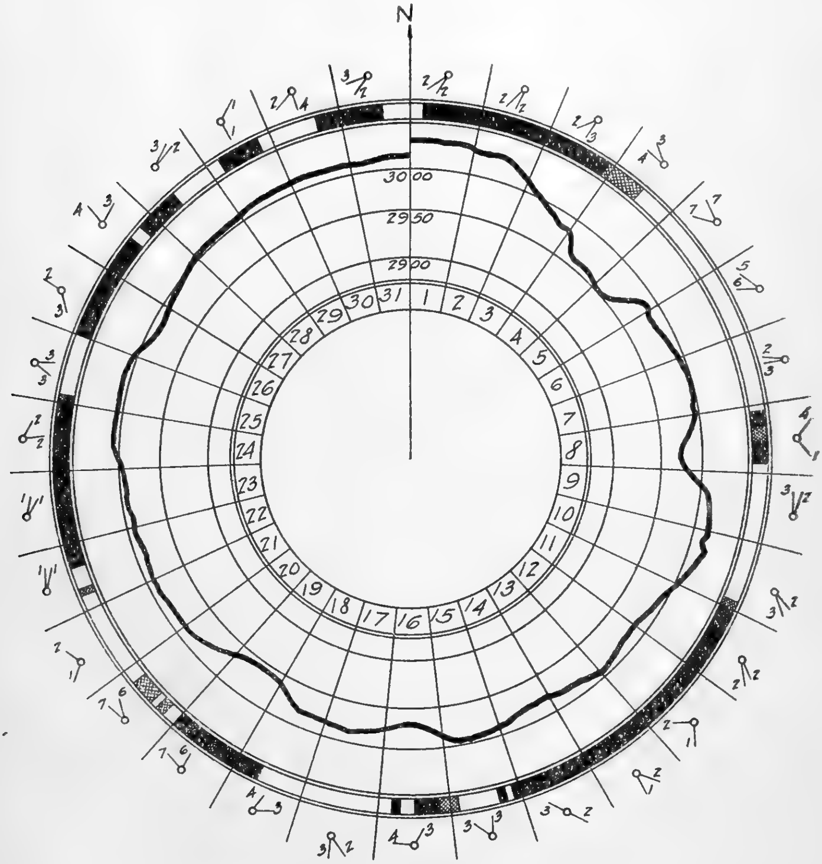

FIGURE 4.—May weather diagram.

About twice as much bad visibility as the patrol's 8-year average normal prevailed during May. On many of the foggy days the weather was really fine the fog being simply a conduction phenomenon limited to the layers of air chilled by contact with cold surface waters, with the sun shining in a perfectly clear sky overhead.

The month was featured by long periods of steady barometer about 30.00 inches in height. Moderate conditions prevailed and there was a marked slowing down and several stagnations in the march of Lows and Highs across the eastern half of North America and out

towards the patrol area. A ridge of high pressure that extended at times unbroken from Greenland to Bermuda was noted during the last half of the month.

The barometric gradients shallowed out markedly as compared with the preceding month. They became strongly suggestive of summer weather conditions with shallow Lows over the land and Highs over the ocean. Only five noticeable depressions are visible in the barometric curve. Four of these are of trivial depth. The most marked Low occurred early in the month, and the passing of its center was followed by nearly 24 hours of northwesterly gales. A few more hours of gales were experienced on the 8th, 19th, and 20th, and no others were encountered during May.

JUNE

Maximum air temperature, 69° F.

Minimum air temperature, 39° F.

Average air temperature, 49.2° F.

Visibility was less than 4 miles 47 per cent of time.

Visibility was less than 2 miles 40 per cent of time.

The ice patrol remained in effect during the first 22 days of June only. During this time poor visibility was experienced slightly in excess of normal. Winds of gale force were experienced only on the 15th. They were from the northwest as the majority of the patrol vessels' gales seem to be.

Summer-time conditions of groups of weak Lows over the continent and a High over the ocean from Bermuda to the northeastward were observed. The persistence of a low pressure area to the northeast of Newfoundland, as in April and early May, was noted.

There were about eight dips in the barometric curve but all were shallow where they passed the patrol vessel and were moving slowly.

GENERAL REMARKS

As in previous seasons a weather map was constructed twice daily on board ship for use in forecasting and in planning the operations of the patrol to the best advantage. The maps were obtained in large part from information in the general synoptic reports broadcast from NAA, Arlington, Va., at 0300 and 1,500 G. M. C. T., well supplemented by means of ship reports from the ice patrol area. A special daily forecast for the patrol vessel was received from the United States Weather Bureau.

The weather information on hand was always available to passing vessels on request. It was usually included, in part at least, in the routine ice broadcasts on account of the marked interest displayed by shipping early in the season in the weather being experienced by the patrol.

Twice daily a coded weather report was dispatched to the United States Weather Bureau, Washington, D. C., and at the end of each patrol cruise a more detailed report was forwarded by mail to the same office.

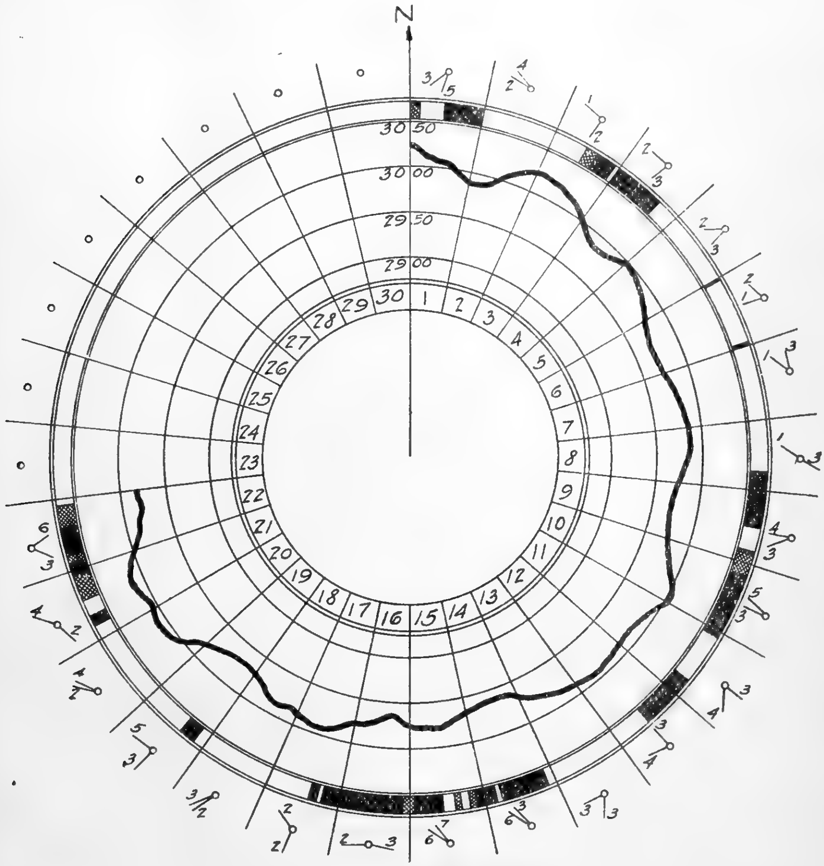

FIGURE 5.—June weather diagram.

Numerous special weather reports were sent to Cape Race for the benefit of trans-Atlantic fliers. During future patrol seasons the ice patrol should be of increasing importance as an observing and collecting station for up-to-the-minute weather reports of value to transoceanic aviation.

DEPTH SURVEY CARRIED OUT BY THE SONIC METHOD

Work was continued during 1928 with that part of the scientific program concerned with determining the bottom contours in the ice patrol regions. The echo or sonic method of depth finding was again used, the *Modoc* and the *Mojave* being both equipped with commercial instruments. Although one of the ice patrol vessels has been fitted with an experimental echo depth finder for several years, this year was the first one in which both patrol ships were equipped to obtain soundings rapidly and easily.

The following brief description is given for the benefit of those who may be unfamiliar with modern sonic sounding methods. Experiments have demonstrated the speed with which sound travels through water under various conditions of temperature, pressure, and salinity. If the time between the outgoing and the return by echo from the bottom of a short sharp note is measured, the depth of water can easily be found out. The principles are simple but in practice many complications arise and the instruments have to be elaborate and ingenious devices.

As might be expected the echoes are relatively much louder in shoal than in deep water. To get results in great depths the oscillators that produce the outgoing notes are strong and powerful. They are placed in the bottom of the ship near the keel. The echoes that come back are picked up by hydrophones in small tanks insulated from sound from all directions but downward.

The echoes are carried electrically to the bridge where an instrument amplifies the intensity of the signals by vacuum tubes until they are audible in head telephones. There is an indicator by the phones which revolves at a constant speed. When the sound goes out the pointer passes a zero mark on the scale. When the sound comes back it is only necessary to notice the number on the scale to which the marker is pointing to get the depth in fathoms instantly.

In shoal water, say under about 60 fathoms, the incoming sound comes back so quickly that it merges with and becomes almost indistinguishable from the loud outgoing one. A different system is used to get the depth in this case, a system much more accurate than that based on the coordination between the ear and the eye of man. The energy coming in from the strong echoes of shoal water is used to cause the flashing of a red neon tube electric light opposite the depth marks on the indicator. The light is carried along on the rotating

disk. As it passes the stationary zero mark on the scale a red flash is seen like a blurred pointer of fire about an eighth of an inch wide. Then when the incoming echoes come in there is another similar red flash opposite the proper depth on the indicator, if all is working well. Very often there are confusing stray flashes caused by breaking waves, outside noises, electric currents, etc.

It is indeed fascinating, and often comforting to the navigator, to be able to steam along taking 150 soundings a minute and watching the depths vary automatically with the red light with such precision as to delineate to the fathom every lump and hollow, every ridge and trough of the ocean floor. The white light or deep-water method is slower because of the time necessary to keep the incoming echoes properly compared with the right outgoing signals, and to allow time for the sounds to go down to the bottom and back at the rate of about 5,000 feet per second. When everything was working properly it was possible to take in depths of 1,000 fathoms or more, about as many soundings in every minute as would be possible with a wire and weight in a 12-hour day.

Notwithstanding their limitations and shortcomings the echo depth finders were invaluable navigational aids on ice patrol. They were especially useful in keeping track of the vessel's position during foggy and cloudy weather and at night, in telling exact points where certain contour lines were crossed, in locating the position of the ship on a line of position or radio bearing line, and in telling quickly the depth of water where an oceanographic station was about to be taken.

The soundings that were taken when the geographical positions of the ships were very well and fairly well known were saved in a smooth record book. Each sounding so recorded meant not just one depth but the mean of several carefully taken over, say, a minute of time, depending more or less on the plainness with which the echoes were heard. If they were faint many would be listened for in order to be sure to have the depth just right.

The accepted soundings were corrected by various amounts ranging up to about 5 per cent to allow for variations in the temperature, salinity, and compression of the water column. The corrections were deduced from the velocity chart published facing page 49 in ice-patrol Bulletin 15, season of 1926. Over 3,000 groups of soundings, taken when it was thought that either latitude or longitude could possibly be wrong by as much as 6 nautical miles, were discarded. Of course, soundings taken during fog, darkness, and in overcast weather were as accurate as those taken when it was clear; but when the position was in doubt, the values could not be used by hydrographers for amplifying the data on charts.

Lists containing over 1,200 good soundings and positions have been forwarded to the United States Hydrographic Office and to the

United States Coast and Geodetic Survey, for their information, in connection with improving the soundings data on the North Atlantic Ocean charts concerned.

As the instruments were a new type never before used on ice patrol, the following remarks are given regarding their action during the different partol cruises. These have been taken in substance from the cruise reports of the commanding officers on the several patrols.

At the beginning of the first cruise only up to 200 fathoms could be sounded with the sonic depth finder on the *Mojave*. Even this was of value in conducting the search for ice, being sufficient to give instant notice when to change course at such times as when approaching or leaving the 100-fathom curve of the Banks. As the patrol went on the depth that could be sounded increased to a maximum of 1,300 fathoms. It was believed that this was due to smoother water which lessened the so-called water noises from whitecaps, and to increasing experience on the part of the operators, for the machine itself had practically no adjustments made to it. It was very encouraging when soundings could be taken in the deep water because of the comparative scarcity of depth values on the chart in the area being searched. The greatest care was taken to keep track of the ship's position at all times in order that the locations of the soundings might be accurate.

The second cruise was started with a systematic gathering of fathometer depths on the *Modoc*. The officers of the deck, by taking soundings every 15 minutes, quickly gained experience in deep water depth sounding and obtained a number of particularly valuable records. Due to the small amount of wave motion and consequent quietness on April 8, audible echoes were obtained in depths up to 2,000 fathoms. On April 10 the apparatus broke down and could not be adjusted until engineers from the maker boarded the vessel at Halifax after the end of the cruise.

It was routine during the third cruise for the officers of the deck on the *Mojave* to get the depth by the echo method every 15 minutes while cruising and every half hour while drifting. Only occasionally was there difficulty, as when the signals were weak in the phones. In all 1,700 successful echo soundings were recorded in the rough book on the bridge during the cruise. Of these 400 were preserved for use in checking the North Atlantic charts. The difference was due to the fixed policy of rejecting for hydrographic use all soundings made when the position of the ship was in doubt due to lack of good sights.

The fourth cruise produced only 22 values of depth for the smooth record. The high percentage of bad visibility, coupled with inability to hear the fathometer echoes in the extremely deep water, where

most of the time was spent, prevented a more numerous result. The weak signals seemed to be caused by trouble in the sound-receiving and amplifying devices. The oscillators in the hull sent out good signals, but it was very difficult to pick up the echoes in the head telephones.

The apparatus worked well during the fifth cruise. Soundings up to 2,600 fathoms were obtained. Besides tabulating for reference 251 depths taken when the ship's position was well fixed, the instrument was an invaluable aid in locating the ship during thick and overcast weather.

The sixth patrol cruise produced 97 values for the depth records; 330 soundings were obtained but the majority were thrown out on account of doubtful positions due to the impossibility of getting enough sights. The short seventh cruise furnished 31 good soundings to be added to the season's total.

It was noted that when the depth finders were in good working order, results in water up to 1,000 fathoms in depth could usually be counted on. The deepest soundings were all made under especially quiet wave and sea conditions. Very likely on ships using less electricity than the electric-drive ice-patrol vessels better results would be obtained. The Diesel-drive cutter *Marion*, on the *Marion* Expedition, shortly after the termination of ice patrol could sound with her instruments of the same make down to 2,000 fathoms consistently, so long as the radio apparatus was not being used. Whenever the near-by transmitter was sending the fathometer was strongly affected with induced noises that entirely blotted out the incoming echoes. Such a condition did not exist on the ice-patrol cutters where the radio room was a long distance aft of the bridge, but no doubt some of the noises that interfered with the hearing of weak echoes were picked up from the numerous strong electric fields on board.

ICE OBSERVATION

The ice particularly watched and tabulated by the international ice patrol is that which, in passing south along the east coast of Newfoundland, gets south of the forty-eighth parallel of latitude. Every recent annual report of the International Ice Patrol Service has contained a section on ice observation. The reader is referred to the 1926 report for a statistical compilation of ice observed in the years to and including 1926, and to the 1927 report for the ice conditions prevailing that year. The figures are based during the actual ice-patrol season on the reports to and the observations of the ice patrol vessels themselves. During the remainder of the year the reports of ice contained in the weekly Hydrographic bulletins of the United States Hydrographic Office and special reports from Cape Race radio-compass station are depended on. A number of ice charts and a discussion of ice conditions month by month during 1928 are given below:

JANUARY

There were no reports of ice during January, 1928

FEBRUARY

No bergs were reported by trans-Atlantic vessels during the month from south of the forty-eighth parallel. Field ice from the Gulf of St. Lawrence was reported from between Cape Breton and Sable Islands. Field ice was reported from several other localities, most of which were north of 47° N., and all of which were north of 46° 30′ N. The other reports were confined to areas off the Newfoundland coast between Cape Race and St. Johns, to the vicinity of 48° 00′ N., 49° 30′ W., and to the vicinity of 47° 00′ N., 47° 30′ W.

MARCH

During this month a number of bergs drifted south along the eastern edge of the Grand Banks, but only one got south of the forty-fifth parallel. Bergs were thickest along the eastern edge a little to the north of this latitude. They were on the whole distinctly below normal for the month in number, however. One berg was reported from a few miles west of Flemish Cap. A few bergs were located along the forty-eighth parallel to the westward of the forty-seventh meridian.

Field ice reached its greatest southerly extension for the year during March. There were two reports of the Gulf of St. Lawrence

PLATE VI.—MELTING FAST IN 60° WATER SOUTHEAST OF THE GRAND BANKS. THIS ICEBERG IS THE SAME ONE AS THAT SHOWN IN PLATE III. IT WAS CLOSELY WATCHED BY THE ICE PATROL FOR 16 DAYS WHILE IT DRIFTED IN A GREAT LOOP FOR OVER 480 NAUTICAL MILES. JUNE 2, 1928

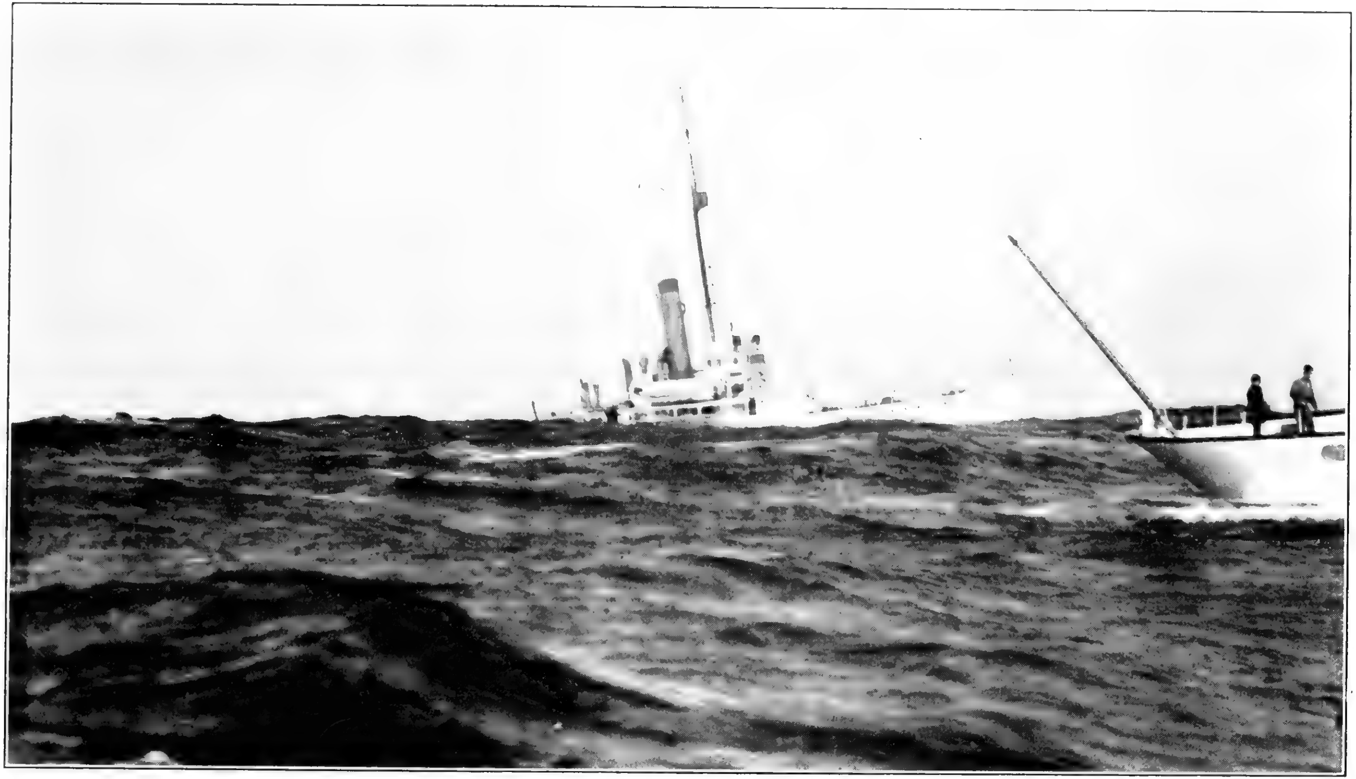

PLATE VII.—THE "MODOC" (LEFT) AND "MOJAVE" (RIGHT) MAKING CONTACT ON APRIL 21, 1928, FOR THE TRANSFER OF THE OCEANOGRAPHIC PARTY AND PATROL RECORDS. THE HEAVY SWELL MADE THE TRANSFER ACTIVITIES AN EXCITING TASK

pack from between Sable Island and Cape Breton Island. The most southerly report was one of this ice from the vicinity of 44° 30′ N., 60° 00′ W. The Canadian authorities in the Department of Marine and Fisheries, Ottawa, at the present writing have more detailed information regarding ice conditions in this western sector.

In the vicinity of the ice patrol's activities field ice was reported as extending northward from 46° 20′ N., 50° 00′ W., and northward from 45° 50′ N., 47° 30′ W. The wording of the several reports indicated that the ice south of the forty-eighth parallel was neither close nor heavy. There were no reports of berg or field ice from along the east coast of Newfoundland, but not enough steamers were traversing the area off this coast to cover it at all well.

APRIL

A great increase in the total number of bergs was noted during April. The feature of their distribution was their scattered southeasterly drift past Flemish Cap and across the C United States-Europe steamship tracks. One berg was reported from an extreme easterly position in 47° 00′ N., 40° 57′ W. Two other bergs were reported from positions east of the forty-third meridian, between the forty-sixth and forty-seventh parallels. The southeasternmost berg of the month disintegrated in the vicinity of 44° 10′ N., 43° 20′W.

Further to the westward one berg was carried south of 43° N. in the vicinity of the forty-ninth meridian. All of the bergs that got south of 43° during the following months did so in the neighborhood of this same meridian.

The bulk of the April bergs were situated along the eastern edge of the Grand Banks from 45° N., 49° W. to 48° N., 46° W. Again, no bergs were reported from near the Newfoundland coast. Rather remarkably, none were reported from west of the fiftieth meridian. The continued absence of steamer traffic from this area makes this negative evidence weak, however. The probability is that there was a considerable quantity of unreported ice there, both berg and field.

The last report of field ice in the Grand Banks area for 1928 was received on the 10th from the vicinity of 47° 30′ N., 48° 40′ W. The Canadian ice patrol service was inaugurated on April 12. On the 13th this service broadcast that there was field ice from the longitude of Cape Breton Island to Cape Race, the fields being heavy to the east and lighter to the west.

MAY

As is normally the case, May saw a greater number of bergs south of the forty-eighth parallel than any other month. Their extreme southeasterly drift was checked by the rapid extension northwestward toward Flemish Cap of Gulf Stream and solar warming. They

were located further west on the average than during the previous month. This caused them to stop in the dead water or to strand along the north edge of the Grand Banks in the region from 46° 40′ N., 52° 00′ W., to 47° 50′ N., 49° 30′ W. A few were carried to the westward in the branch of the Labrador current that sets past Cape Race through the Gulley. The westernmost berg of this group just crossed the fifty-fourth meridian off St. Marys Bay, Newfoundland.

Seven bergs from the large number concentrated along the northern half of the eastern edge of the Grand Banks during the preceding month escaped being stranded along the edge or being curved off to the northeast by the inshore edge of the warm Gulf Stream influence. These seven floated down the narrow band of cold water along the eastern edge off the Tail of the Banks and were swept across the forty-third parallel between the fiftieth and forty-eighth meridians. By the 31st one of them reached 40° 47′ N., 48° 54′ W. Three days later this berg reached its extreme southerly position in 38° 59′ N., 48° 57′ W., which was 126 sea miles farther south than any of the 1927 ice drifted.

No field ice was reported from the Grand Banks area in May. The only field ice report to be received by the ice patrol during the month was one of the St. Lawrence pack that by then had dwindled inshore to the vicinity of 47° 40′ N., 60° 00′ W. The ice season in the gulf was open and light and terminated unusually early. For authoritative information regarding field ice to the west of Cape Race, one should address the Department of Marine and Fisheries, Ottawa, Ontario, as that department is in charge of the ice-patrol service conducted by the Canadian Government for the benefit of shipping entering St. Lawrence Gulf and River ports.

JUNE

Only eight different bergs were sighted or reported from south of the forty-sixth parallel during June. Six of these were south of the forty-third parallel. These six were all disintegrated during the first week of the month by the relatively high surface temperatures resulting from continued solar warming and Gulf Stream mixing. Three reasons can be given for the fact that no bergs are known to have crossed the forty-third parallel after June 5: 1. Probable actual weakening of Labrador current. 2. Temperatures of surface layers south of forty-eighth parallel well above freezing, even in the Labrador current, which, coupled with 1, would cause bergs to disintegrate before getting far south. 3. Failure of large supply of bergs to Labrador current where it rounds the northeast promontory of the Grand Banks. The ice was on the average even farther west in the ocean during June than it was during May. Many of the bergs were close to and stranding upon the coast of

the Avalon Peninsula of Newfoundland. Two groups of bergs were stopped or stranded on the northern part of the Grand Banks in the vicinity of 47° 20′ N., 50° 50′ W., and 47° 30′ N., 49° 40′ W. Neither of these groups was located far enough to the eastward to be favorably situated to serve as the origin of southerly berg drifts.

Vessels apparently began using the Belle Isle steamship tracks on the relatively early date of June 21, for 23 bergs and several growlers were reported to the international ice patrol on that date from between Greenly Island and 52° 30′ N., 53° 00′ W. No field ice was sighted by or reported to the patrol vessels during June.

JULY

Fifty-five bergs were south of the forty-eighth parallel. All of them were within a 50-mile radius of Cape Race, Newfoundland.

AUGUST

Five bergs were south of the forty-eighth parallel. All were in the same area as the July bergs.

SEPTEMBER

No bergs were south of forty-eighth parallel in September.

OCTOBER

Four bergs drifted south of forty-eighth parallel during the month. Three of these were close to Cape Race and one was about 120 miles to the eastward.

NOVEMBER

Four bergs got south of the forty-eighth parallel. Ice was noticeably farther east in the ocean than in four preceding months.

DECEMBER

No bergs south of forty-eighth parallel up to time of finishing this manuscript for printer, January 4, 1929. Very likely a few reports of ice sighted in December are yet to come in.

The above monthly discussions and the charts following this section give a general idea of the ice distribution southeast of Newfoundland below the forty-eighth parallel throughout the year. For a narrative account of the ice seen, together with the attendant observations and conditions, see the 1928 cruise reports at the beginning of this pamphlet.

As in former years the ice patrol kept track of and recorded the drift of as many bergs as possible during the season. The paths taken are shown on Figure 12. The longest track is over 480 sea miles in length and represents the results of 16 days of actual trailing and tracking by the ice patrol vessels.

Figure 12 also shows the known risks from bergs that the United States-Europe steamers experienced in April, May, and June, 1928. The ice-patrol broadcasts help to minimize these risks, but in times of fog and darkness real safety can lie only in radically reduced ship speeds and judicious caution.

SUMMARY

Month	Bergs south of 48° N. in 1928	Bergs south of 43° N. in 1928	Bergs south of 48° N. normally	Bergs south of 43° N. normally
January	0	0	3	0
February	0	0	10	1
March	14	0	36	4
April	156	1	83	9
May	190	7	130	18
June	87	6	68	13
July	55	0	25	3
August	5	0	13	2
September	0	0	9	1
October	4	0	4	0
November	4	0	3	0
December	0	0	2	0
Total	515	14	386	51

From the above figures it will be seen that the total number of bergs known to have been south of the forty-eighth parallel in 1928 was considerably above normal during the greater part of the heavy ice season. On the other hand, the number of bergs to drift south of the forty-third parallel was distinctly subnormal. Some of the latter bergs got into the circulation southeast of the Tail of the Grand Banks, however, and attained extremely low latitudes before melting.

Field ice was distinctly below normal in amount about the Grand Banks as well as inshore to the westward. Its southerly extension was never great and it disappeared from the picture relatively early.

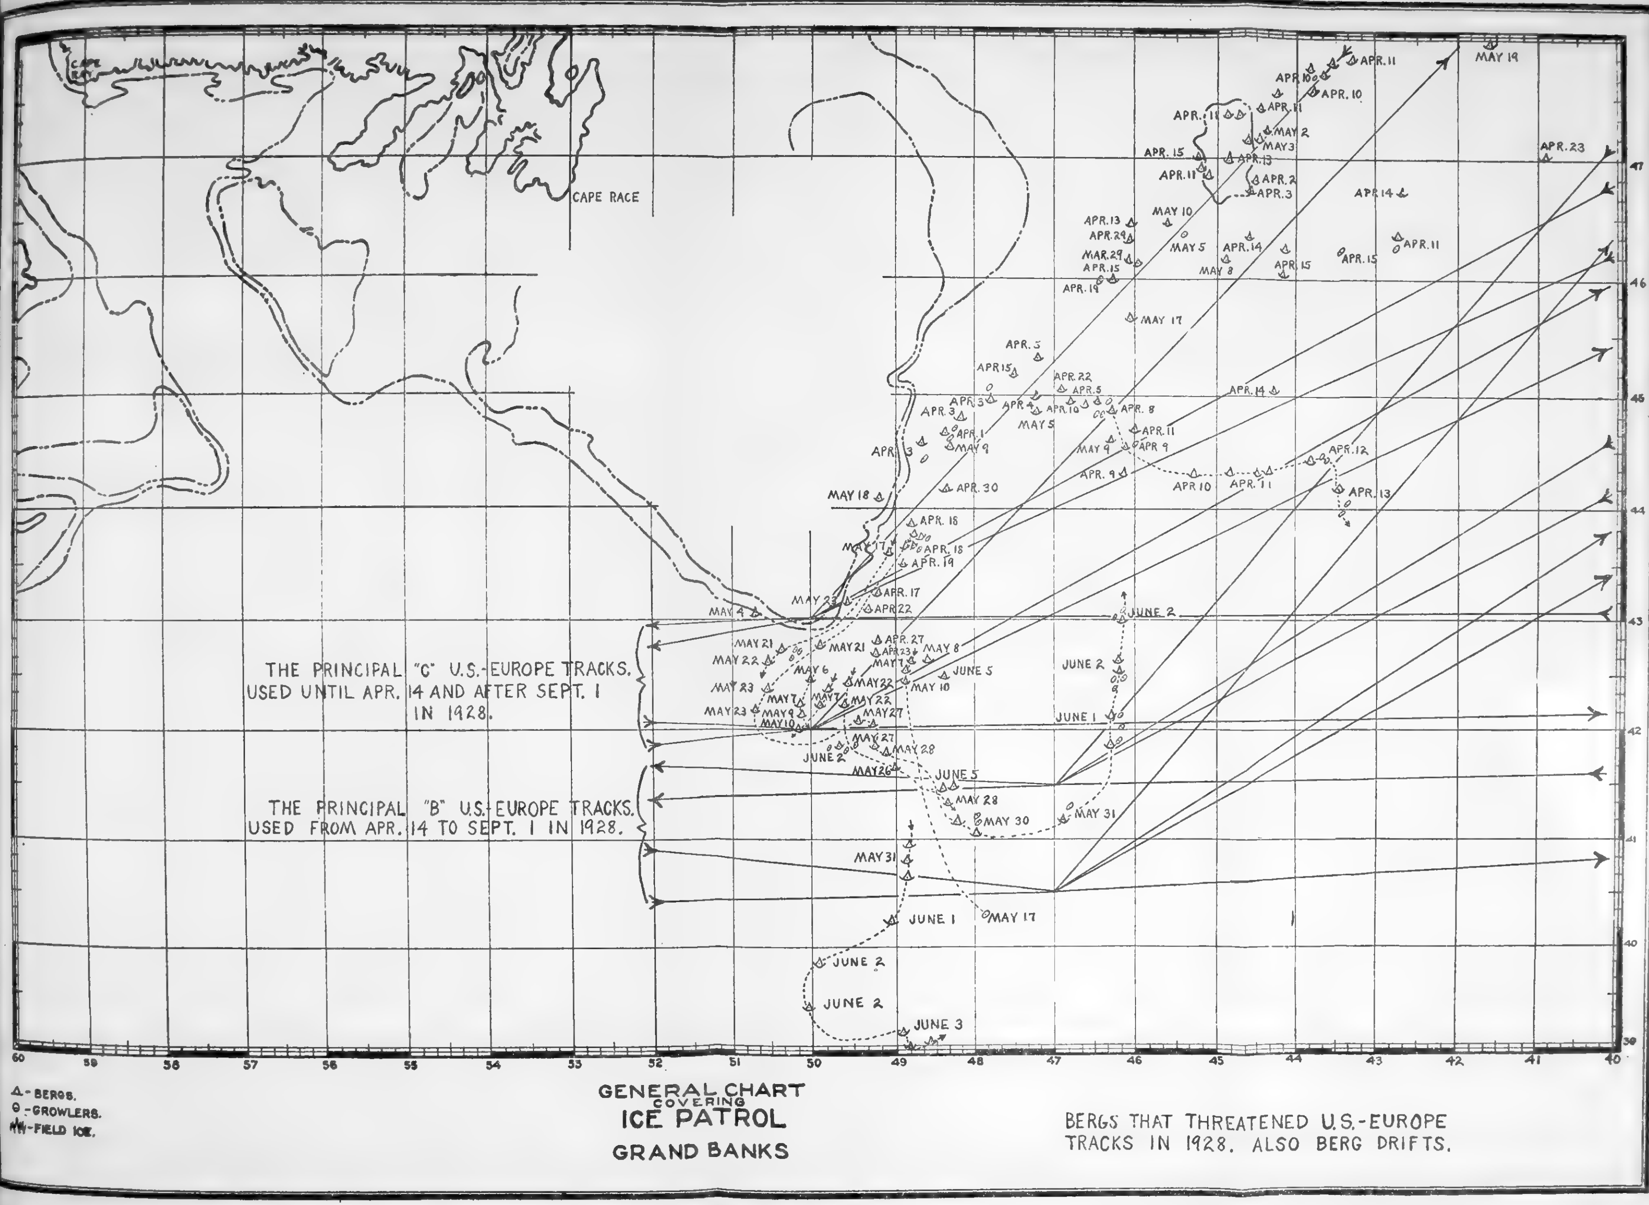

FIGURE 12.—Positions of icebergs that approached or crossed the United States-Europe steamship tracks in 1928, together with drift tracks of all icebergs that the Ice Patrol was able to follow

OCEANOGRAPHY

During the ice patrol season of 1928 no detailed large area current maps were made by the hydrodynamic method as the threatening ice situation prohibited intensive oceanographic work. The United States-Europe C tracks were adhered to by shipping until April 14, when they had either been crossed or were immediately menaced by no less than 28 bergs.

The patrol recommended the shifting of the tracks to more southerly ones many days before the desirable action was taken. No reason is known why the C tracks were adhered to so much longer than usual in 1928, unless it was that the trans-Atlantic track conference again expected a fairly safe northerly distribution of ice such as was experienced in 1927. When the B tracks were finally used they were adhered to longer than absolutely necessary. Looking back at the actual manner in which ice was distributed month by month it can now be seen that had the tracks been shifted south to B one month earlier than was done and shifted back to C two months earlier than was done, 1928 would have seen one month's less use of the longer tracks and at the same time have had a safer distribution of sum total ocean crossings than was actually the case.

After the B tracks went into effect the patrol was but little freer to take stations than before. The drifts of several bergs actually on or across the B tracks had to be followed. The rest of the time had to be devoted to searching for new bergs coming down to and threatening the B tracks from the little crossed fog areas immediately to the north. The oceanographic stations, being secondary in importance to the actual ice scouting, had to be taken about when and where possible.

The positions of the 95 stations taken during 1928 are shown in Figure 13. The station distribution would have been differently arranged if the patrol vessels had been less under the necessity of scouting and trailing bergs as above noted, and many more stations would have been taken also, approaching the ideal of a close checkerboard arrangement of observations, repeated every two weeks over the areas to be investigated.

The scientific observer and his oceanographic assistant were different persons than those who took and worked out the stations during previous seasons. The new men gained considerable experience during the course of the spring.

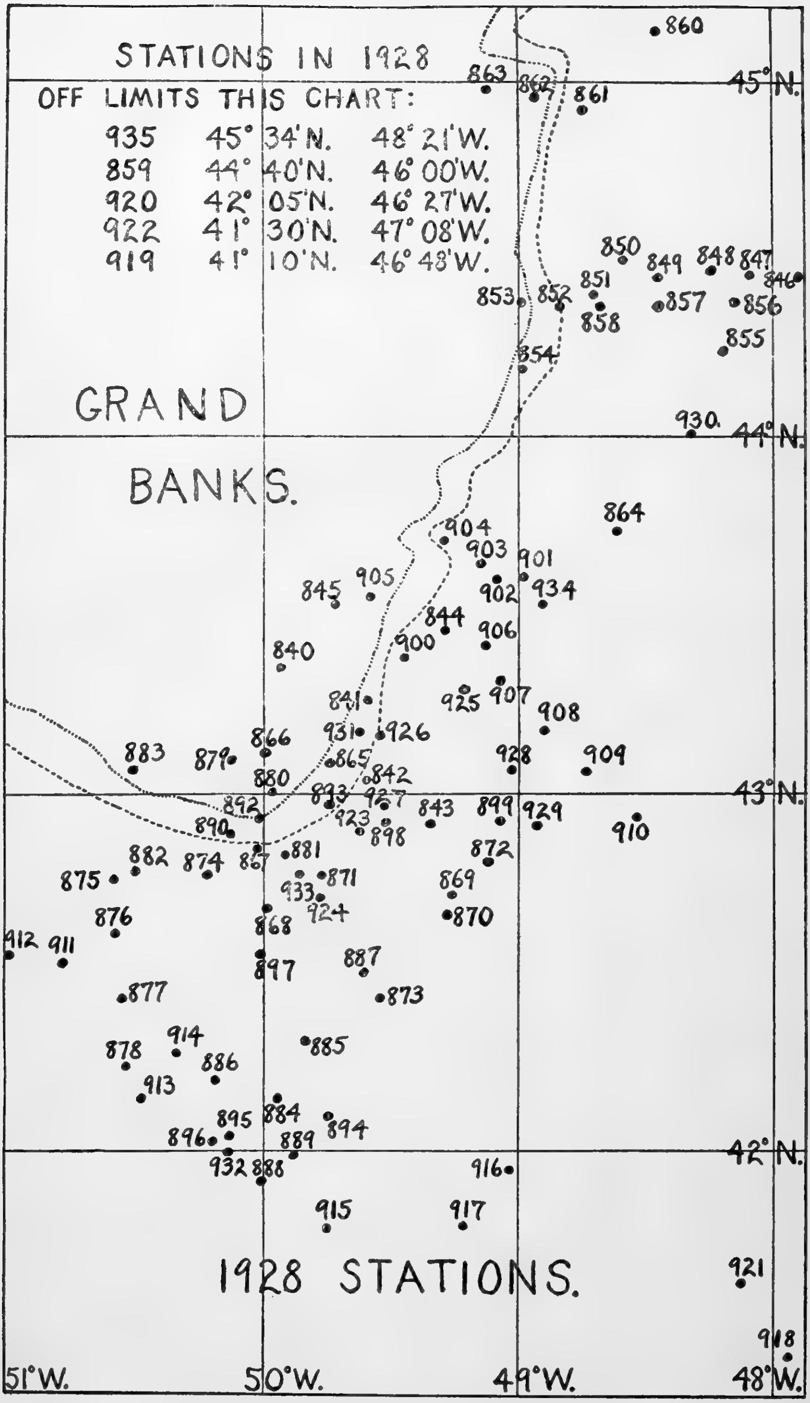

Figure 13.—Distribution of oceanographic stations

Throughout 1928 the salinities were determined and the stations were computed at sea, as in 1926 and 1927, very quickly after the actual stations were occupied. In running the electric salinity cabinets the need was felt for standard water of dependably known salinity for calibrating and frequent check purposes. The carboys of tested water on hand from the previous year were of somewhat doubtful salinity.

Graphical curves of temperature with depth should be made at every station before the ship is started ahead. Questionable—that is, seemingly erratic or unreasonable—values of temperature should mean the retaking of the whole station at once, or at least the retaking of the doubtful and adjacent levels. Irregular values of salinity should be watched for also in the same manner. When they are found the water from the level in question should be retested, this time in another electric cell from the one first used. As the salinities can not be determined for some little time after the stations are finished, the ship will always be too far from the station to permit the procuring of a new bottle of water. If reasonable results can not be obtained, interpolation between adjacent levels must be resorted to. Where interpolated values were used in 1928 the fact is noted in the table of station data. So delicate is the balance of the various water masses in the sea that the greatest methodical care in all work connected with the taking and computing of the stations is the only insurance against gross errors in the final results.

The 1928 stations have been divided into seven groups or sets as shown in figures 14 to 20. Each set is made up of stations taken within a period of time short enough to permit the hydrodynamic values to be compared with reasonable safety for general current work.

The arrows on the current charts were put in much like wind arrows could be put on a weather map if the barometric pressures at a number of observing stations were known. The four group figures by the dots that represent the various stations show in tenths of dynamic millimeters the height of the average sea surface above 728 dynamic meters that must have existed above the 750 decibar pressure level. (A decibar is a pressure equal to one-tenth of an atmosphere. A dynamic meter is approximately the same as an ordinary meter. It is a vertical unit of distance that varies from place to place in the same ratio as the force of gravity varies.) The four figure distances were computed from the known distribution of salinity and temperature in the water of the various levels at each station.

Seven hundred and fifty decibars was the deepest pressure level that was sampled during the 1928 ice patrol. If more time were available it would have been advantageous to go down to the 1,000 or even the 1,500-decibar levels at the deeper stations in order to be sure of determining all the current. It is believed, however, that not a

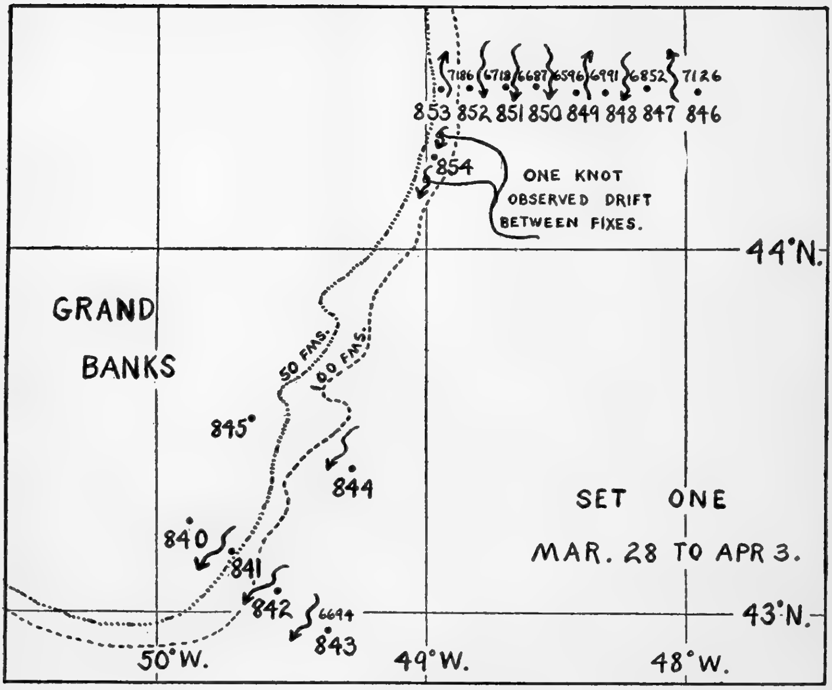

FIGURE 14.—Current tendency diagram

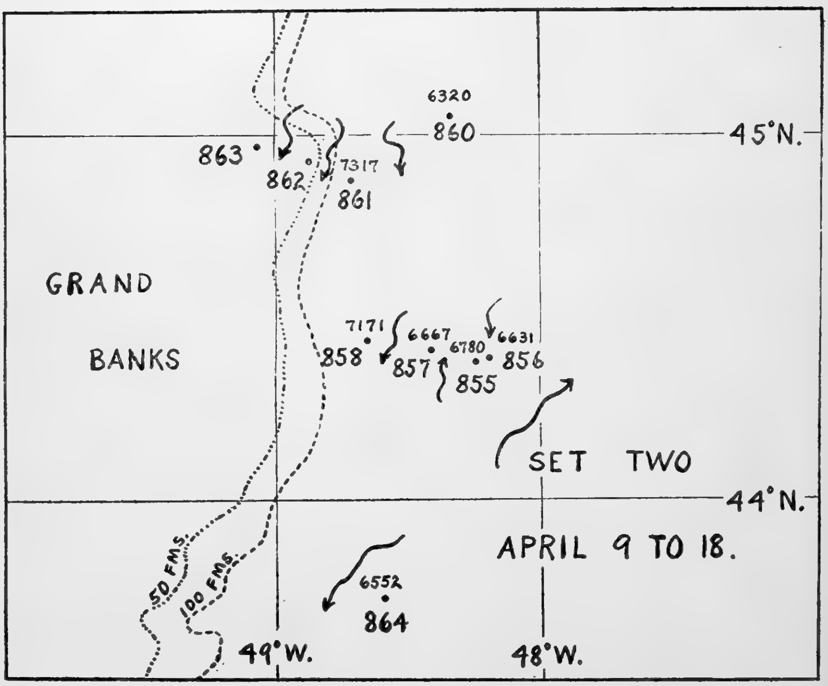

FIGURE 15.—Current tendency diagram

great deal of accuracy is lost by neglecting the small variations in conditions that usually exist below the 750-decibar pressure level in the sea.

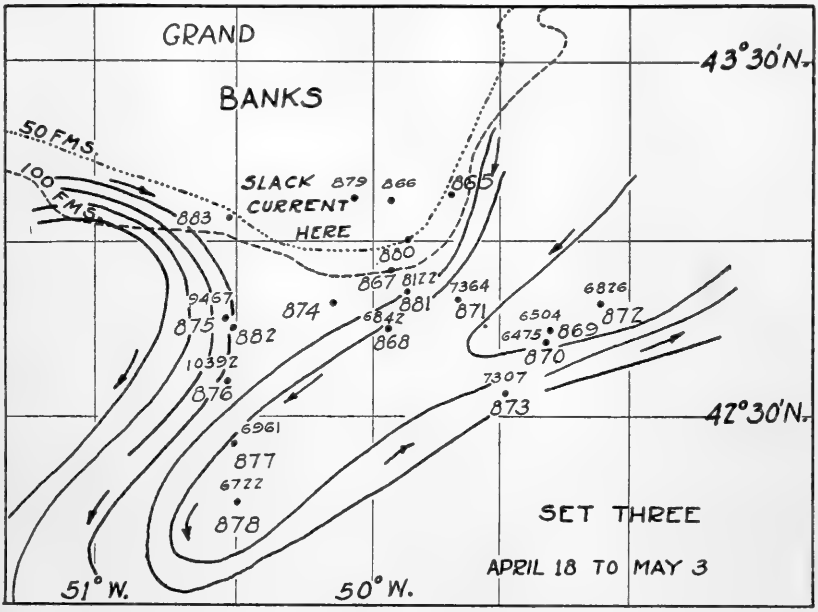

FIGURE 16.—Current map

Where the four-group figures are larger it means that, because it is lighter, the water is puffed up so that the average height of the sea surface is heaped up more above the local mean sea level than where

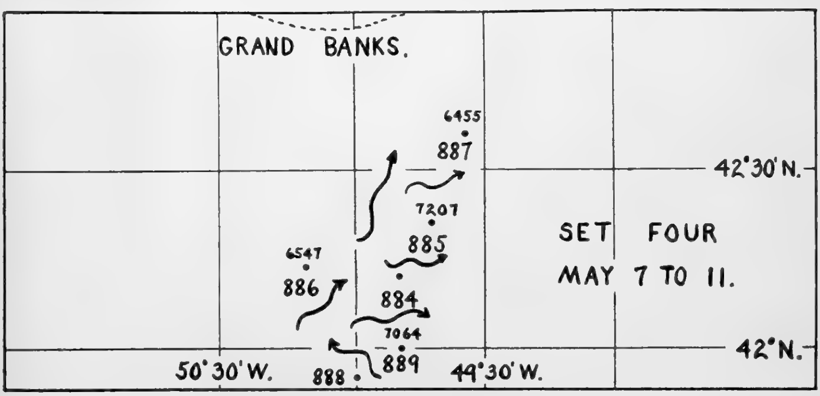

FIGURE 17.—Current tendency diagram

the figures are smaller. Highs in the sea are thus formed, and these north of the equator, both by theory and by actual observations in many open seas, have clockwise currents circling about them. These

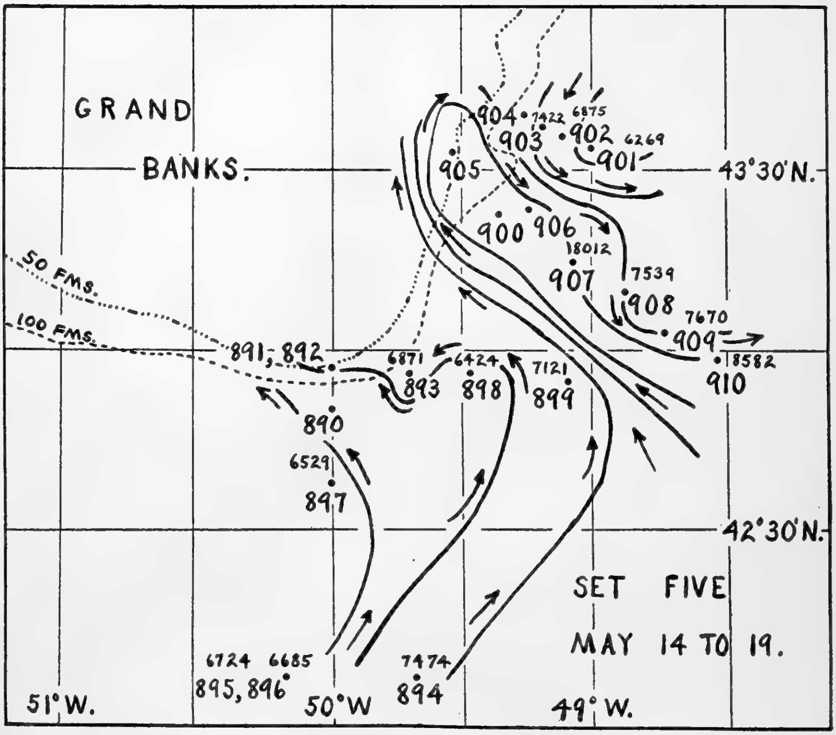

FIGURE 18.—Current map

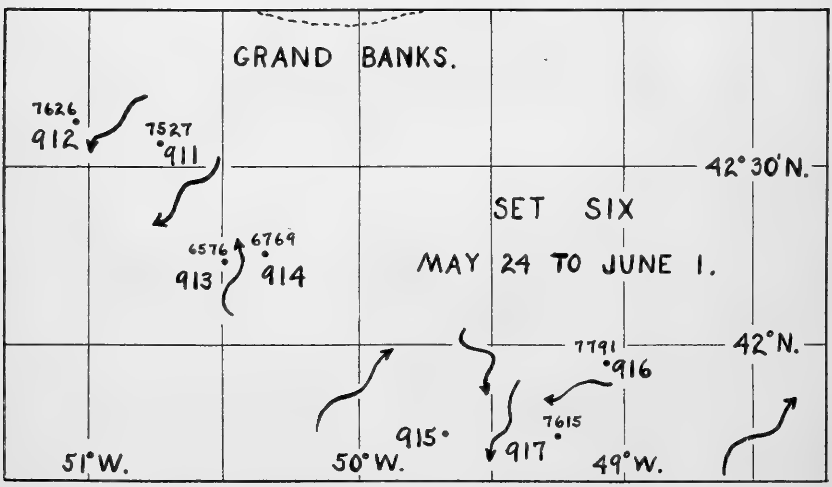

FIGURE 19.—Current tendency diagram

currents flow much like the surface winds do about a barometric anticyclone in the atmosphere, and for the same reasons of gradient gravity pull as modified by earth rotation. The Lows, on the other hand, are actual depressions in the sea surface caused by denser water which is depressed because it is heavier than that surrounding it. Such hollows have counterclockwise currents eddying about them in the northern hemisphere just the same as the barometric cyclones have counterclockwise wind systems about them. In reality the water simply tries to find its own level by slipping down off the Highs and down into the Lows, but it is deflected about 90° by the effect of earth rotation and so spirals around and around them.

The arrows on the current maps show the computed directions of general flow of the local ocean currents and therefore show the prob-

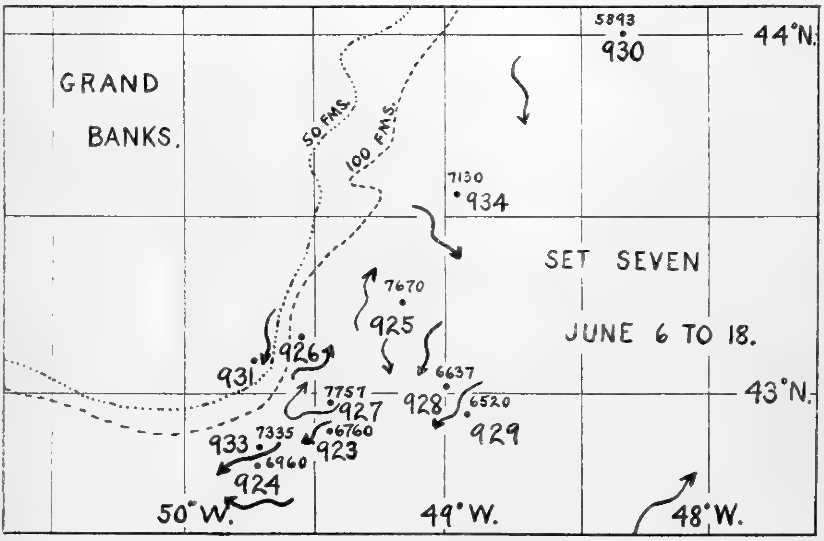

FIGURE 20.—Current tendency diagram

able paths of any bergs that might be located in the vicinity at the time. The bergs, being but relatively little influenced by winds and shallow surface drifts, move primarily in accordance with the main gradient circulation of the sea. United States Coast Guard Bulletin 14, A Practical Method for Determining Ocean Currents, was used to make the current maps. That pamphlet explains all the principles involved and then gives explicit directions for working the oceanographic stations and using the results obtained to make the current maps.

Where no four-figure number is given by a station it is because either the depth did not extend down to the 750-decibar level, or if it did, then, due to errors of observations, no reasonable value for the depth of the 750-decibar level below the surface could be computed.

The arrows could be drawn in almost all cases, however, and not just where the 750-decibar levels were computed, for where the latter values were absent higher decibar levels between the stations could be compared.

The station groups when worked out showed densities, and hence current sets and drifts by computation, that were quite logical in all cases when a few stations, obviously in error, were thrown out of the picture. Nothing like an ideal detailed current map could be made, but a number of the stations were so grouped that the width of the cold south-flowing Labrador current was determined at several places and times along the southern half of the eastern edge of the Grand Banks.

The nearest approaches to real current maps made were sets 3 and 5 that are shown in Figures 16 and 18. In these two groups there was enough of a network of stations to permit the construction of dynamic contour lines. These lines actually represent the relief of the average level of the sea surface with wave motion eliminated, and are drawn connecting points that are the same height above a base level that in each case was taken as the deepest sea hollow on the map. When contour lines are drawn in, a much more accurate picture of the oceanic circulation can be formed than where scattered stations, or even good but distantly separated lines of stations at right angles to the Banks, are used.

The currents flow as shown by the arrows in directions parallel to the contour lines. The water, as stated above, always tries to flow down the hill, but there is no outlet at the bottom and earth rotation continually deflects it, so it has to flow along just about parallel to the contours with the higher water on the right hand in the northern hemisphere when facing in the direction of flow.

Sets 3 and 5, studied with and without contour lines, give such radically different pictures of the circulation that it can now be definitely stated that the only distribution of stations that will give results of practical value to the ice patrol is a thick checkerboard network of stations. This is partly on account of the confused eddying conditions in the waters off the Tail of the Grand Banks. In an area where there was less turbulence, where the currents flowed along with less mixing and interaction—as is probably the case farther southwest in the Gulf Stream, and farther north in the Labrador current—a single line of stations taken at right angles to the supposed stream flow would be of value.

The two contoured current maps give just a hint of the complexity and irregularity of the currents that prevail about the Tail of the Banks. The picture of the circulation that would be gained by studying the dynamic relations of the line of stations, as 905 to 910 in one of these figures, would give a simple Labrador current and offshore Gulf Stream

flow and would be misleading instead of useful, in view of the bulb and eddy circulation that actually exists.

Even though scant opportunity was afforded for making station networks, a good many single stations were taken for information and practice, as just before the start of a day's scouting, just after dark when stopping for the night, by a newly found berg, or when stopped by dense fog. These isolated observations gave information about the lower water levels much like that which could be obtained of the underlying strata by scattered borings in a field, the rock conditions under which it was desired to ascertain. The solitary stations could usually be linked together with others not too far distant in space and time to permit the obtaining of fairly reliable and accurate current tendency diagrams.

The three figures—21 to 23—that immediately follow page 74 are the salinity and temperature sections. These have been constructed for the places where lines of stations were taken nearly at right angles to the Grand Banks shelf. The information on which they are based is found in the table of oceanographic station data, but the figures make this information easier to grasp at a glance. In fact the figures show the tendency of the cold fresh water from the north to hug the Bank slope so well that there is no necessity for making detailed comment here.

Following the oceanographic sections come Figures 24 to 30, which are the surface isotherm charts. These were drawn one for each patrol cruise from information on hand at the end of the several 15-day periods. The temperatures on which these maps are based were for the most part sent in from passing vessels, though the patrol vessels themselves on each cruise were able to supplement the surface observations received by radio with their own observations made along their tracks. The temperatures sent in by passing vessels are carefully recorded and analyzed, as they afford the patrol valuable information concerning currents and probable drift of ice.

A tremendous volume of reports made the temperature conditions of the surface waters particularly well recorded in the vicinity of the United States-Europe tracks area. Ships on the Canada-Europe tracks sent in many temperature reports also, but only sparse reports came from the band between these two main traffic lanes.

When the F and B tracks are in use, as they normally are a large part of the ice season, the seldom traversed ocean band between the lanes averages about 300 sea miles wide. Poorly covered for water temperatures means to the patrol poorly covered for ice conditions also. It is this band of ocean intermediate between the great traffic lanes that the ice-patrol vessel regards with much suspicion and to which a great deal of time for scouting for bergs must be given.

Because of its limited location and now well-known tendencies the Labrador current between the steamer lanes could be fairly easily searched for ice by a one-ship-on-duty patrol if good visibility normally prevailed. Unfortunately such is not the case. The cold water about the Banks so projects into the warm ocean that winds from southwest through south to northeast bring warm air to the Labrador current and dense low fogs are produced. The thick weather prevails over the critical blind area such a high percentage of the time during the ice season that great difficulties in successful scouting are experienced. The cold current can not be covered as it really ought to be covered by the patrol. Sometimes the bergs once found are lost during fog and storms and are not located again before they melt entirely.

Therefore, notwithstanding the accumulated experience of the ice patrol and all the advanced scientific methods that have been used, trans-Atlantic traffic even on the southernmost A and B lanes should not depend blindly on the patrol for safety. On the northern lanes the ships fully expect to meet ice at any time when near the Grand Banks, so they are usually quite cautious. The ships on the southern tracks should follow their example during times of fog and darkness. The ice patrol with the information and equipment on hand does all that it is possible for it to do toward locating and keeping track of the ice so that safety along the southern lanes may be assured. In closing this report, however, it is deemed best to sound a note of warning. Shipping is urged to realize the physical limitations of the patrol in its struggle with the obstacles of nature. Steamship companies and captains are requested not to let recent comparative freedom from disaster to lull them into a false sense of security. They must do their part to insure safety while crossing the probable ice area by exercising sound judgement, reducing speed, and being cautious during all times of low visibility, even when the patrol's broadcasts indicate that they are well clear of all known ice.

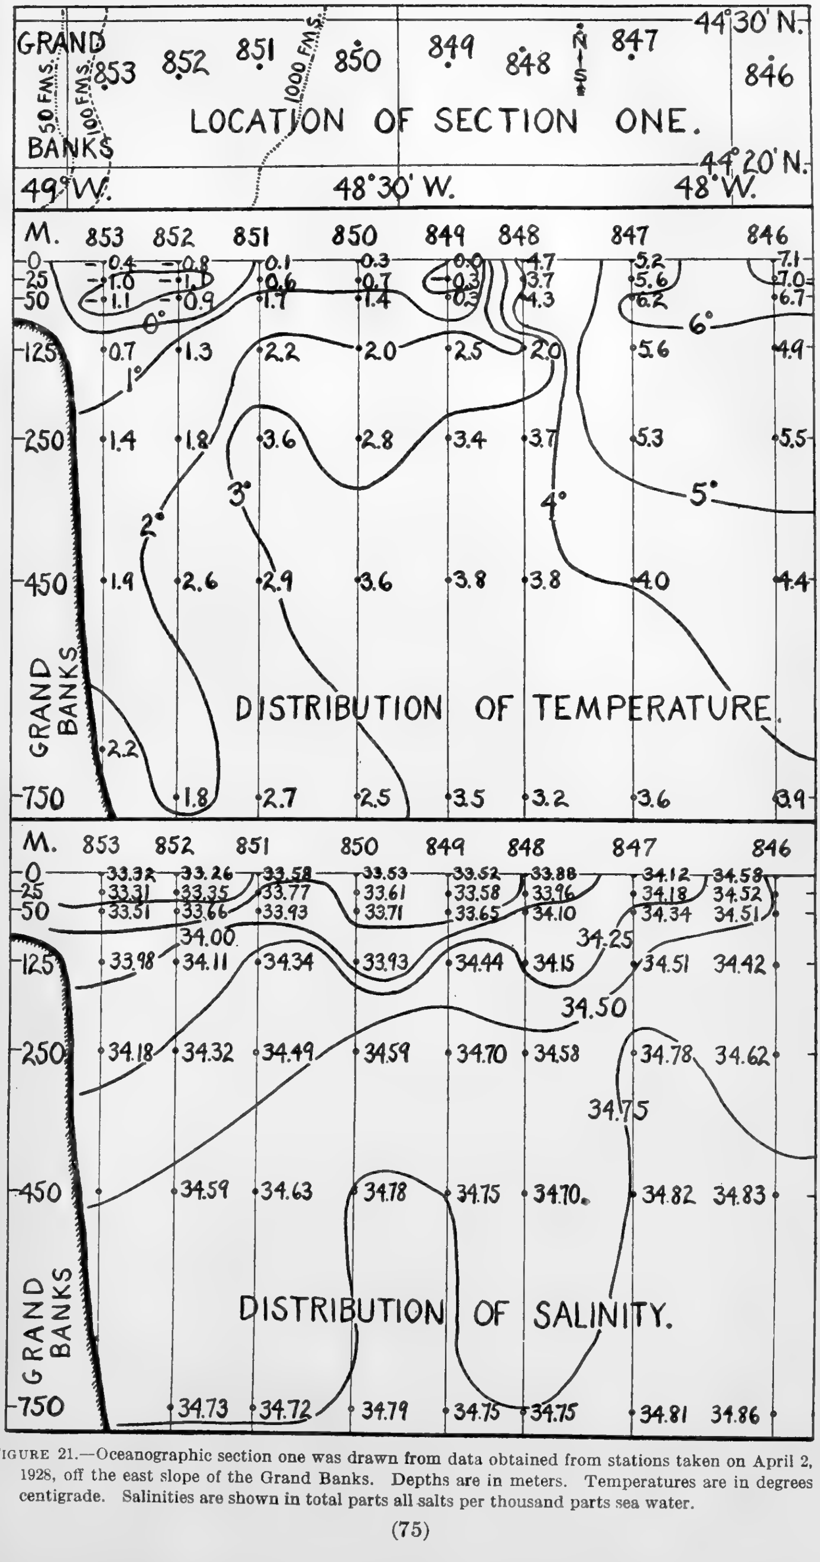

FIGURE 21.—Oceanographic section one was drawn from data obtained from stations taken on April 2, 1928, off the east slope of the Grand Banks. Depths are in meters. Temperatures are in degrees centigrade. Salinities are shown in total parts all salts per thousand parts sea water.

[1] Values by interpolation on account of loss of water sample, failure of thermometers to work, etc.
[2] Values obviously in error, but included for completeness and to show what was actually recorded.

[1] Values by interpolation on account of loss of water sample, failure of thermometers to work, etc.
[2] Values obviously in error, but included for completeness and to show what was actually recorded.

WASHINGTON : 1930

TABLE OF CONTENTS

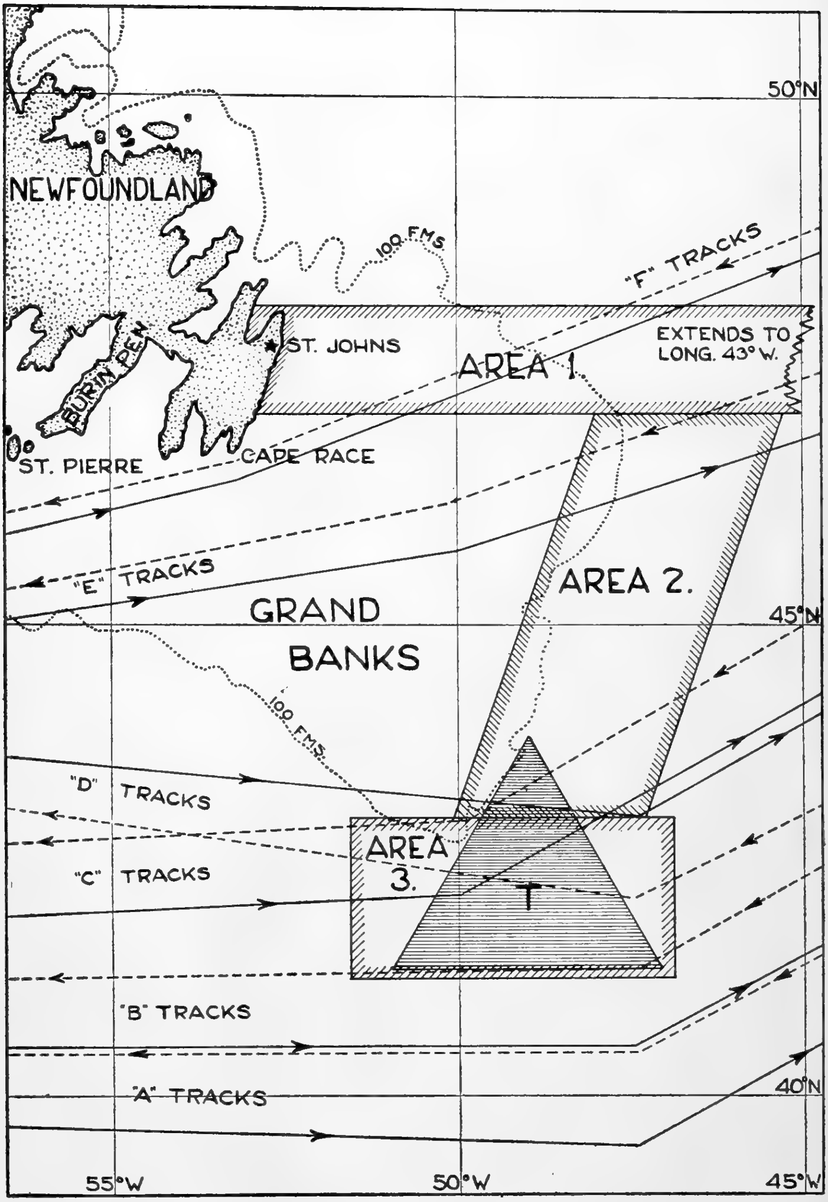

FIGURE 1.—The scene of the principal activities of the International Ice Patrol. Tracks A, B, and C are routes to and from United States ports. Tracks D, E, and F are routes to and from Canadian ports. Areas 1, 2, and 3 make up the "melting area" described in the chapter on oceanography. Fully 90 per cent of the icebergs that drift south of the 48th parallel each year disintegrate in this "melting area" covering in all some 74,000 square sea miles. The triangle "T" is a very critical area and must be frequently searched out for ice by the patrol vessels themselves

INTRODUCTION

In 1855 Matthew F. Maury, later to be known as "The Pathfinder of the Seas," was a lieutenant in the United States Navy and in charge of the Naval Observatory at Washington, D. C. In January of the above year he began strenuously advocating in the interests of safety separate travel lanes for eastbound and westbound traffic between Europe and America. The cause of the great concern was a disastrous collision between eastbound and westbound vessels, in which 300 lives were lost. There was some opposition at first, but in the course of a few years a mounting list of disasters through collision forced such a system of tracks to be put into effect. Although the danger of collision between vessels was thus greatly lessened, there remained the problem of the ice menace that threatens in the vicinity of the Grand Banks off Newfoundland each spring.

In 1890 Hugh Rodman, then an ensign in the United States Navy, was ordered to proceed to Newfoundland and Nova Scotia to make investigations relative to the ice. The information that he obtained was combined with that accumulated through reports for many years from shipping and was published by the Hydrographic Office as a pamphlet entitled "Report of Ice and Ice Movements in the North Atlantic Ocean." A partial list of disasters contained therein shows that from March 19, 1882, to April 16, 1890, there were no less than 14 vessels lost and about 40 vessels seriously damaged in the North Atlantic due to ice. Among these were many trans-Atlantic steamers that had collided with icebergs. The Hydrographic Office admitted that if reports had been received of all the fishing and whaling vessels lost or damaged the list would have been much larger.

A study of the records up to 1890 clearly showed that the ice came down from the north in larger amounts and extended farther to the southeast of Newfoundland in some years than in others. The heavy ice years were the ones when the greatest toll of trans-Atlantic vessels was taken. Continual efforts were made to gather reports of ice conditions, and the United States Hydrographic Office gave out its information to the shipping interests as quickly and in as much detail as possible. Other than accumulating ice reports on shore from shipmasters, nothing new was done to combat the danger until after the world had been horrified by the *Titanic* disaster of April 14, 1912, in which over 1,500 persons lost their lives. The *Titanic* sank on her maiden voyage shortly after collision with an iceberg in latitude 41° 46′ N., longitude 50° 14′ W.

Resolved to prevent the repetition of such a tragedy and to meet the almost universal demand for a patrol of the ice zone to warn passing vessels of the limits of danger from day to day during the ice season, the United States Navy scout cruisers *Birmingham* and *Chester* were ordered to inaugurate such a service that was to continue until the end of the ice season of 1912. Very opportunely, radio had been developed and brought into use by this time, so that much more information could be gathered and disseminated by a ship on patrol in 1912 than would have been possible even a few years earlier. During the season of 1913 the patrol was undertaken by the Treasury Department and performed by the Coast Guard cutters *Seneca* and *Miami*.

At the International Conference on the Safety of Life at Sea, signed at London on January 20, 1914, the high contracting parties provided for the inauguration of an international service of ice observation, ice patrol, and ocean derelict destruction in the North Atlantic. The Government of the United States was invited to undertake the management of this triple service, the expense to be defrayed by the high contracting parties in a fixed proportion. The proposition was favorably considered by the President, and on February 7, 1914, he directed that the (then) Revenue Cutter Service begin as early as possible in that month the international ice-observation and ice-patrol service. Each year since then, with the exception of the years 1917 and 1918, a patrol has been maintained by the Coast Guard. Two of the largest and best equipped of the United States Coast Guard cutters have been ordered from their home stations and detailed to keep close watch on the ice so as to be able to warn shipping promptly and effectively of the position and movements of the menacing bergs and floes. The cutters inaugurate the patrol very early in the spring, as soon as the ice begins to push south along the eastern edge of the Grand Banks, and one of the two always remains on duty in the ice area until summer time conditions so melt back the limits of ice that it no longer constitutes a serious menace to the trans-Atlantic lane routes.

The three southernmost pairs of tracks between North America and Europe (see fig. 1, United States Coast Guard Bulletin No. 17) carry the fastest as well as the largest amount of traffic and are the lanes that the ice patrol strives particularly to guard. They are laid down well to the south of the usual limits of field ice, so the patrol does not have to contend with that sort of ice itself or to warn the United States-Europe traffic of it to any great extent. The ice patrol's great problem is berg ice from the Greenland ice cap. The solid, massive bergs persist in the ocean much longer and extend to far lower latitudes before they melt than does the field ice. For instance, about 1,000 miles east of the American coast in 1928 one berg drifted to the

latitude of Washington, D. C., just south of the thirty-ninth parallel, before it disappeared. During the same year the most southerly report of field ice, outside of that which was reported from the approaches to the Gulf of St. Lawrence, was far to the north of the latitude of Portland, Me., or Halifax, Nova Scotia. The field ice of the Grand Banks region is broken off from the outer limits of the Arctic pack ice, or is formed locally on the surface of the sea along the North American coast to the northward of Cape Race, Newfoundland. Bad as it is for shipping north of the forty-seventh parallel at times, it is, when compared with the bergs, a relatively short-lived ephemeral affair, even along the northern tracks that run across the Grand Banks.

The patrol vessels do not attempt to destroy the bergs, as many people have been led to think through reading erroneous statements that sometimes get into newspapers and news reels after demolition experiments have been carried out on the ice. Except under very favorable conditions, bergs are dangerous to board in the open ocean because of the wash of the sea against their hard steep sides. The risks are augmented by the fact that the sea about them is usually icy and boisterous in early spring. Later on when conditions have ameliorated the bergs are much more frequently cracking up, dropping off large overhanging ice masses, and turning over.

The ice patrol's experiments have shown that mining operations with high explosives, in the few cases when they are practicable are almost useless. The large bergs are so deep lying, massive, and hard that the explosion of a hundred pounds, more or less, of T. N. T. has very little effect other than to increase the size of the hole in which the charge is placed and to shake off a few pieces of ice already about to fall. Gunfire is even more futile than mining. Well placed shots will sometimes bring down a few tons of ice into the sea, but when it is considered that 500,000-ton bergs are not uncommon and that only about one-fourth to one-sixth of the mass of a berg projects above water to serve as a target, the futility of this method of attack becomes apparent.

The series of experiments on the destruction of bergs undertaken by Prof. H. T. Barnes, of McGill University, have been followed by the ice-patrol authorities with interest. His thermite charges seem to give a little more promise of success than any other method evolved to date, but there are grave practical difficulties connected with placing the thermite in the heart of the bergs where it can act most effectively. Up to the present time, at least, it would seem that the only practicable thing that can be done is to watch, and to keep shipping advised of the changing positions of the various southernmost bergs and ice fields until in the natural course of events they melt. They disappear rather rapidly as they drift south into warmer waters during the advance of spring. As stated above, the field ice is disposed

of very rapidly in the open ocean about the Grand Banks. Even the bergs have a comparatively short life there. Each one of the latter presents a special problem of melting, depending on its size, shape, and solidity, as well as on the sort of weather and water that it encounters. Along the northern edge of the Gulf Stream the accumulated observations of the ice patrol show that the largest and most resistant bergs can last only about two weeks.

The thing that most hampers the patrol in its service of information is the prevalence of fog in the ice-infested regions. Experience shows that quick advantage must be taken of every spell of good weather if anything approaching an efficient information system is to be maintained. The critical areas just north of the southernmost steamer lanes must be searched again and again for ice during the course of the season. At night, and also when dense Grand Banks fog closes in, the patrol vessels usually stop and drift. This procedure not only insures that no bergs are passed unnoticed because of bad visibility, but also conserves fuel, which permits higher speed cruising when the weather is clear and bright.

Much scientific work has been done in conjunction with the ice patrol and much statistical data regarding the ice has been gathered and published in the annual ice-patrol bulletins. A great deal more is now known about the Labrador Current and the Gulf Stream in the vicinity of the Grand Banks than was known when the *Titanic* went down. There is still much work to be done before the great variation in the severity of the ice seasons from year to year can be fully explained, however, and before the final drift tracks of bergs that are seen off the eastern edge of the Grand Banks can be predicted with confidence.

The international ice patrol for the season of 1929 was carried on by the United States Coast Guard cutters *Tampa* and *Modoc*. The *Mojave* acted as the stand-by vessel, but she was not called upon for active duty on patrol. Commander Thomas M. Molloy, in addition to being in command of the *Tampa*, was commander, international ice patrol. Commander Philip F. Roach was in command of the *Modoc*. Lieut. Commander Noble G. Ricketts was detailed as ice observation officer and remained at sea with two enlisted men as assistants throughout the patrol season in order to aid the commanding officer of the vessel actually on duty in ice-patrol matters and to keep a continuous and uniform record of the year's work for this annual report.

Halifax, Nova Scotia, was the base for fuel and supplies during the ice season. The *Tampa* and *Modoc* made alternate cruises of about 15 days each in the ice regions, this time being exclusive of the five or six days occupied in going to and from the base.

Eight times each day radio broadcasts giving locations or limits of all known ice in the North Atlantic were transmitted for the benefit of shipping approaching the ice-patrol area. The different bergs, if not again sighted or reported, were kept from five to seven days in the broadcasts before they were dropped.

The probable drift tracks of critical bergs were indicated when possible. The surface isotherms were very successfully used to estimate probable berg drift tracks and to determine limits of ice areas to be searched. The isotherm curves were drawn partly from information obtained by the ice-patrol vessels themselves, but mainly from careful plotting and analysis of the surface water temperature reports received by radio from cooperating vessels. The value of these reports can not be overestimated, and it is hoped that their number will increase annually. When every vessel crossing the ice-patrol area, particularly those off the most usually traveled routes, reports regularly to the patrol, then the latter will be able to render the most efficient and useful service possible.

Special messages were drafted and sent to any ship that inquired for special information relative to ice, weather, routes, and similar matters. The successive positions of vessels as plotted from their water temperature reports were carefully watched. Whenever it was apparent that a ship was following a course leading toward danger the master was warned, safer courses or other suitable precautions being suggested. Once each day a compilation of all ice sighted or reported during the previous 24 hours was transmitted by radio direct to the United States Hydrographic Office at Washington, D. C. These reports were given wide dissemination among shipping circles by the hydrographer of the United States Navy.

The scientific work carried on by the patrol in 1929 was similar to that of previous years. Deep-sea soundings were obtained by the echo method at frequent intervals for the purpose of improving the bathymetrical charts of the ice-patrol area. Surface and subsurface temperatures and salinities were determined at numerous oceanographic stations. By the latter means it is possible to study the local currents generated where the Labrador Current meets the Gulf Stream, and to compare conditions prevailing in the different localities cruised over with those that prevailed there during former months and years. To facilitate reference and comparison the various sections of this bulletin are on the same subject matters and have been arranged in the same order as those in the 1928 Ice Patrol Bulletin, the 1928 publication itself being modeled on the form that has practically become standard during recent years.

CRUISE REPORTS

THE FIRST CRUISE, "TAMPA," APRIL 1–19

The *Tampa* left Boston, Mass., to inaugurate the 1929 international ice patrol at 12.30 p. m. on April 1. The 950-mile run to the Tail of the Grand Banks consumed four days. On April 6 a search to the northeastward for ice was started from a point about 50 miles south of the Tail, two bergs and several growlers being located in the vicinity of 42° 40′ N. 49° 30′ W. before night. Detailed reports of ice received from the Cape Race radio station and from steamers crossing the Banks showed that ice conditions were extremely bad north of the forty-fourth parallel.

April 11 saw completed the search of the cold current lying off the eastern edge of the Grand Banks between the forty-fourth parallel and the "B" United States-Europe tracks, then in effect. Four additional bergs and several growlers were located and numerous sail of the French fishing fleet were sighted. The fishermen, all about 30 days out from France, were heading west toward the Banks. Upon request, four of these vessels with sick or injured men on board were visited by the *Tampa's* medical officer.

Until the 14th the patrol remained near 42° 13′ N. 49° 33′ W., guarding the southernmost ice. During this time the first oceanographic stations of the year were occupied southeast of the Tail. On the 12th the scientific work was interrupted by a short search for the French fishing vessel *Sylvanna*, which, according to radio advices, had been abandoned on fire about 40 miles northeast of the *Tampa*. She must have sunk shortly after her entire crew of 32 had been rescued by the Swedish steamship *Malmen*, for the patrol never found other trace of her than a few charred timbers.

On April 14 the *Tampa* cruised northward up the cold current to see what ice was coming down. No new bergs were located, but patches of slush ice were seen near 43° 10′ N. 49° 45′ W. From the latter point courses were run to search out the area southwest of the Tail, where a berg was located in 42° 16′ N. 51° 04′ W. on the 15th. The next two days showed that its drift was about 6 miles per day toward the southeast. Word was received on the 16th that the Canadian ice patrol in the Gulf of St. Lawrence had been inaugurated by the ice breaker *Miquela*. The 18th and 19th were spent drifting southwest of the Tail in the first prolonged dense fog of the season. The *Modoc* arrived at a rendezvous in this area at 12.55 a. m. on April 20 and received the ice-observation party and the patrol records.

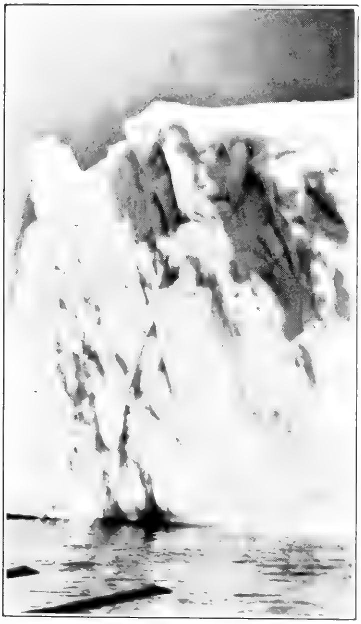

PLATE I.—Icebergs often keep their sides clifflike and perpendicular by repeated calving. When undercutting along the water line reaches a certain point the overhanging ice masses fall down into the sea, leaving a rough surface like this. Taken from a ship's boat July 15, 1929, in latitude 41° 34′ N., longitude 48° 58′ W.

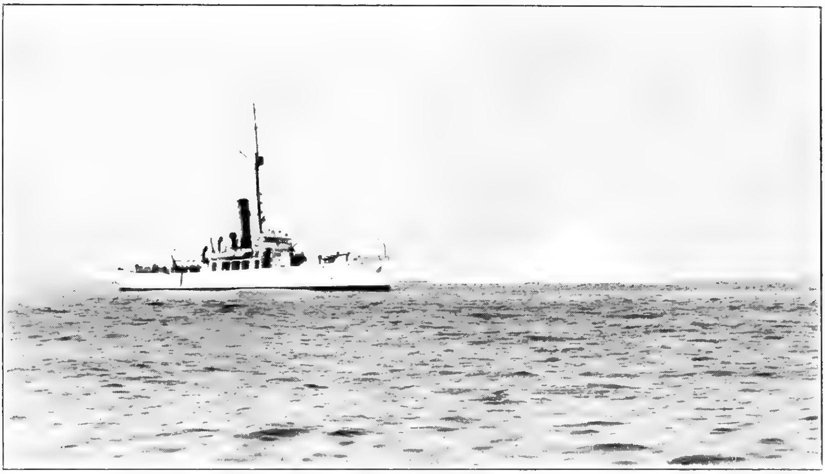

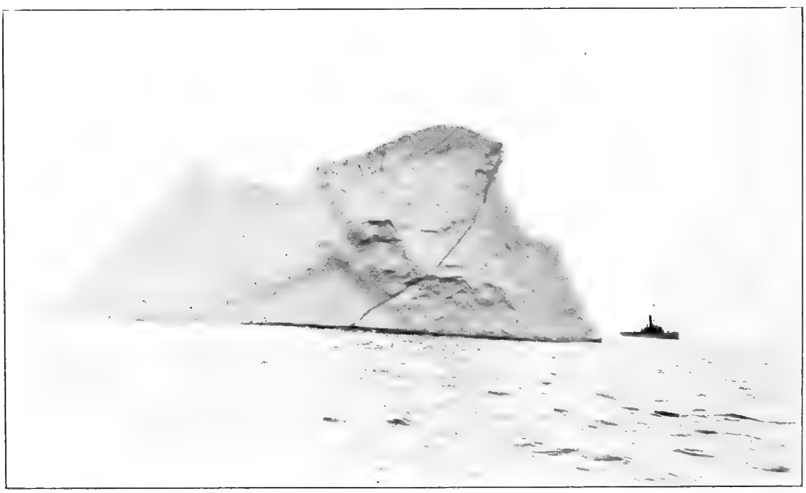

PLATE II.—The *Modoc* and a 500,000-ton iceberg. Difference in relative size of vessel and iceberg is due to the fact that in one case the ship is beyond iceberg and in other the iceberg is beyond ship. Taken from ship's boat on July 18, 1929, in latitude 42° 28′ N., longitude 50° 05′ W.

Numerous reports from passing vessels on the 17th and 18th showed that the "B" tracks were seriously threatened by a southeastward push of scattered bergs toward 42° 40′ N. 44° 50′ W. Besides mentioning this new development in the regular broadcasts, special warnings were sent out at appropriate times. Recommendation to shift the United States-Europe tracks 60 miles south from the "B" to the "A" lanes was radioed to Coast Guard headquarters on the 19th.

Earlier in the cruise the shift north of the Canadian tracks from "D" to "E" on the regular scheduled date of April 10 had been viewed with concern because heavy field ice and many bergs were known to be along the "E" tracks between the forth-seventh and forth-ninth meridians. On the 4th the *Tampa* had advised against the putting into use of these tracks until further notice. As a matter of fact they remained almost impassible until the end of the first cruise. Many liners, instead of attempting to follow them, detoured around the southern end of the heavy field ice that extended to near 45° 00′ N. 48° 30′ W. Those vessels that did use them were generally subjected to considerable delay and, it is believed, to no little danger.

About 75 different bergs drifted south of the forty-fifth parallel during the first cruise, the majority keeping within 75 miles of the eastern edge of the Grand Banks. The patrol vessel guarded particularly the southern extension of these bergs to make sure that the "B" tracks south of the Tail would not be crossed by unreported ice. All the bergs watched south of the forty-third parallel were small water-glazed ones near the end of their careers.

The weather in general was rather boisterous, with many strong breezes and a few southwesterly gales. Visibility was remarkably good throughout most of the period. Overcast nights were the rule, but the sun nearly always penetrated the cloud blanket from late morning to midafternoon.

Altogether eight oceanographic stations were occupied in scattered locations. The salinities were determined in the electric salinometer and the stations were fully computed before the relief by the *Modoc*. Dr. R. MacDonald, a marine biologist from Harvard University, accompanied the *Tampa* on the first patrol cruise for the purpose of collecting specimens from surface and intermediate levels with townets. He made 11 successful hauls at favorable times and places, the results of which will be used by him for furthering knowledge of the North Atlantic fauna.

One hundred and sixty reports of ice were received by radio from ship and shore stations. In addition the patrol vessel herself sighted and recorded the position of ice fifteen times. Ten vessels were given special ice information. This was usually sent on request, but on the 12th the *Gripsholm*, observed from her water temperature

reports, to be running toward danger in darkness, was warned on the initiative of the patrol.

The isotherm curves on the cruise chart were made up in large part from 908 sea water temperature reports received by radio from 149 different vessels. The *Tampa's* own hourly readings were used to supplement the 908 values received from shipping crossing the ice-patrol area. Unusually cold surface water, as low in temperature as 28° F., was repeatedly encountered in the area just south of the Tail of the Grand Banks. The southerly extension of cold water and ice, particularly the latter, was greater than during the corresponding period last year.

THE SECOND CRUISE, "MODOC," APRIL 19–MAY 3

The *Modoc* left Boston, Mass., at 10.30 a. m. on April 15, 1929, to relieve the *Tampa* on ice patrol. Dense fog prevailed at the rendezvous in 42° 30′ N., 51° 40′ W., on the night of April 19, but radio-compass bearings enabled contact to be made readily and searchlights penetrated the fog sufficiently to enable the ice-observation party and the patrol records to be transferred by boat as soon as the two ships met.

On the morning of April 20 word was received of the French fishing vessel *Eskualduna*, abandoned in sinking condition at 43° 40′ N., 51° 15′ W. The report being very recent and the location within eight hours' run, course was shaped for the derelict. By the evening of April 21 the area within 30 miles of the reported position had been searched. Good visibility had prevailed, but no wreckage was seen. It is believed that the vessel sank.

The French fishing vessel *Notre Dame de Bizeux* was spoken to on the Banks northwest of the Tail on the morning of April 22. She had not seen the *Eskualduna* nor heard of her abandonment, but she did have on board the master and 17 men of the *Chevalier Bayard*, a French fishing vessel that had foundered on the 16th due to taking water and to inability to run the pumps. The 18 other members of the crew of the lost vessel were distributed among three more vessels of the fishing fleet in the vicinity. The master of the *Notre Dame de Bizeux* desired the *Modoc* to take the rescued fishermen ashore from his vessel. Upon being informed that the *Modoc* could not land the men for two weeks on account of ice-patrol duties, he drafted a radiogram for transmission to the French hospital ship *Ste. Jeanne D'Arc*, requesting that vessel to relieve him of the extra men for whom he had no suitable accommodations. Continuing south, the *Modoc* on the 22d sighted seven bergs and several dozen growlers in the cold water just west of the Tail. The North Atlantic track agreement shifted from track "B" to track "A" on the 22d. Much field ice

and many bergs were reported during the first three days of the cruise from along the "E" tracks.

As April 23 was foggy all over the patrol area, no searching could be done and no ice reports were received by radio. Two oceanographic stations were taken. Advantage was taken of the fine clear weather of the 24th, 25th, and 26th to search for ice between the Tail of the Banks and the westbound "B" tracks. None was seen and none was reported in this area. On the 24th a very rough sea remained from the storm of the night before, but this gradually flattened out. On the 25th and 26th a current of 2.7 knots setting to the northeast was encountered along the forty-second parallel between the forty-ninth and fifty-first meridians. This was along the cold wall where the sea temperatures were observed to be varying between 58° F. and 38° F. within a very few miles.

No searching could be done and there was very little ice reported on the 27th, 28th, 29th, and most of the 30th because of fog. This thick weather prevented the ice-patrol vessel from supplementing with her own observations the reports made by passing vessels during the first cruise of ice in the southeastern sector.

On May 1, the visibility again being excellent, a search was started in the cold water just south of the Tail. The next day courses were run well offshore up the eastern edge of the Banks. Six bergs were sighted between the forty-eighth and fifty-first meridians north of the forty-third parallel on the two days. During the fine clear weather of the 2d no less than 56 reports of ice, all from north of the forty-third parallel, were received from other vessels. Phenomenal visibility prevailed on the second, for a medium-sized berg that later proved to be approximately 40 miles to the northeastward, was visible from the bridge at noon.

May 3 was spent searching southwestward from the forty-fourth parallel along the 100-fathom curve of the Banks. In general good visibility continued during this day, though fog banks were met at times as the ship proceeded toward a rendezvous with the *Tampa* in 42° 40′ N., 51° 40′ W. Contact was made some hours before dawn on May 4 and the relief of patrol was effected at once in the usual manner.

During the second cruise the southernmost ice was located for the most part along and just offshore of the 100-fathom curve of the eastern edge of the Grand Banks. It was in great amount north of the forty-fourth parallel. Early in the cruise field ice was reported along with the bergs as far south as latitude 44° 40′ N. By the end of the second cruise, however, the limits of the field ice had retreated to the forty-eighth parallel. Strong Gulf Stream effects prevented any bergs from drifting south of the forty-second parallel. The warm water during the cruise also removed the menace to the "B" tracks

that was threatening on April 18 in the vicinity of the forty-fifth meridian. A few bergs were reported from positions well over on the Banks. Such ice as reached the latitude of the Tail was forced close around it to the west. Although the threatening situation that existed for the "B" tracks at the beginning of the second cruise seemed to have passed for the time being, the bergs remained in such great quantities along the eastern edge of the Banks until the last of the cruise that it was thought inadvisable to recommend a shift of tracks north from "A."

Six oceanographic stations were taken and computed during the cruise. The salinities of the samples of sea water were determined on board quite satisfactorily by the method of chemical titration. As was done on all cruises, frequent soundings were made by the echo method.

Considerable fog was experienced during the second cruise, but there were also long intervening periods of fine, clear weather. During the cruise a marked transition from blustery spring conditions to more moderate summer conditions with predominating light southerly breezes took place. In the ice-patrol area the sun's rays increased in strength noticeably and commenced to warm effectively the surface layers of the sea on clear days.

Special ice information was sent to seven vessels; 957 temperature reports were received from 134 cooperating vessels. The water temperature and weather reports in addition to showing the location of the cold and warm currents, helped the patrol vessel to tell just what sections were being effectively searched by shipping and enabled her to devote her own efforts to the critical areas and to areas from which no reports were being received. During the second patrol period 203 reports of ice were received from ship and shore stations.

THE THIRD CRUISE, "TAMPA," MAY 4–19

After the *Tampa* took over the ice-patrol duty low visibility due to mist and fog patches prevailed until the 5th, on which date a search for ice was started up the eastern edge of the Banks from the latitude of the Tail. Six bergs were located in the cold stream south of the forty-fourth parallel. On the 6th the largest of these, when revisited, was found to have drifted 24 miles, 160° true, in 24 hours to 43° 04′ N., 48° 49′ W.

The 7th and 8th were foggy, but on the 9th visibility was good again. No search was started on this day, however, because a member of the crew had been operated upon for appendicitis on board the evening before and it was desired to keep the ship as steady as possible for his benefit. He rapidly recovered without complications. Twenty-five ice reports came in from north of the forty-fourth parallel during the day. One of the bergs along the

eastern edge close to the forty-sixth parallel was said to be 300 feet high.

On May 10 a second thorough search was made of the axis of the Labrador Current between the forty-fourth and forty-third parallels. One large berg was found in 43° 00′ N., 49° 20′ W. As it was drifting rapidly southward at first, it was trailed closely until the night of the 15th, when it was lost during a southerly gale with fog. Even while in waters about 34° F. in temperature this berg was seen to turn over completely at least once a day, and more frequently to list deeply. It must have been so finely balanced that slight uneven melting was sufficient to cause it to change position. Being massive and rounded, very few pieces were detached as it rolled. The southerly drift was checked at about 42° 20′ N., 49° 30′ W., from which position the movement of the berg was to the westward past the Tail, always a number of miles north of the cold wall.

From 42° 48′ N., 50° 47′ W., the drift of this berg was southward again. When lost on the 15th it was approximately in 42° 15′ N., 50° 40′ W., only 40 miles north of the westbound "B" tracks, but presumably about to be carried eastward along the cold wall. The failure of the above berg to drift south along the forty-ninth meridian into the Gulf Stream on the 11th made it seem certain that the "B" tracks were safe for the time being. Accordingly, on the evening of the 12th a message was sent to Coast Guard headquarters recommending that the United States-Europe tracks be shifted north from "A" to "B" until further notice. On the night of April 15 word was received from the Hydrographic Office that track "B" would become effective westbound on May 18 and eastbound on May 25.

During the third cruise an unusually large number of bergs were reported as between the forty-sixth and forty-eighth parallels, between longitudes 46° W. and 48° W. There were at times some remnants of field ice in the central portion of this area. Field ice and many bergs and growlers were reported by the few vessels that crossed the ice area north of the forty-eighth parallel. South of the forty-fifth parallel the bergs were comparatively few in number and widely scattered. The ones observed by the patrol decreased in size but slowly because the water around them was only 2° to 4° above the freezing point of fresh water. Eight oceanographic stations were taken and worked out during the cruise.

The fog that caused the patrol vessel to lose the berg trailed from the 10th to the 15th cleared at 2.30 p. m. on the 17th. The remainder of that day and all of the 18th were spent searching south of the Tail to relocate the southernmost known ice. The berg of the 15th could not be found again, but another berg was sighted late in the afternoon. A feature of the last two days of the patrol was a flood of

reports from between the forty-eighth and forty-ninth parallels along the "F" or Cape Race tracks, which began to be used on the regular scheduled date, May 16. Fog and rain on the "F" tracks on the 17th caused many liners to stop and drift and cut down somewhat the extraordinary number of these ice reports.

At 12.30 a. m. on May 19 the *Modoc* was met at 42° 55′ N., 52° 25′ W. There the ice-observation party and the patrol records were transferred and the relief of the patrol was effected.

Weather during the third cruise was remarkably fine and moderate on the average. There were no gales until the moderate westerly one of the 14th, which was accompanied by high barometer and clear skies. A depression that passed to the north of the patrol on the 16th caused a few hours of southerly gales with fog. Fine visibility with a clear-cut horizon was the rule, fog being experienced during but 22 per cent of the time.

One thousand and eighty-two surface water temperature reports were received from 180 vessels. These were, as always, of great value for use in planning the patrol's searching, for estimating the probable drift and life of ice, and for keeping track of shipping crossing the ice-patrol area. Two hundred and ninety-eight ice reports were received from ships and shore stations. Seventeen vessels were given special ice information.

THE FOURTH CRUISE, "MODOC," MAY 19–JUNE 2

Search courses on May 19 revealed two bergs south of the Tail. The one found in 42° 44′ N., 51° 13′ W., had drifted west-southwest at the rate of 1.3 knots since left by the *Tampa* on the 18th. On the 20th fog prevented continuance of the search for the southern limits of the cold-water area, but on the 21st fine visibility again prevailed, with the result that the ice patrol and cooperating vessels practically cleared up, for the time, the existing ice situation in the waters south of the forty-third parallel. Four bergs and one growler were believed to constitute all the ice south of the Tail, and all of these on the 21st were north of latitude 42° 30′ N. On the 21st no less than 76 reports of ice were received, a new high record for one day, proving that extremely bad ice conditions were persisting north of the forty-sixth parallel.

Unfortunately, dense fog on the 22d prevented the *Modoc* from relocating the southwesternmost ice and determining its drift toward the westbound "B" tracks. Word was received during the day from Cape Race that Cabot Straits and the Gulf of St. Lawrence were clear of ice.

When the fog cleared on the morning of May 23 another search of the southwestern portion of the cold-water area was started. Visibility gradually improved as the day went on, but no ice was located north of the "B" tracks. The 24th and 25th were spent searching

for ice in the cold water southwest of the Tail. A growler in 42° 53′ N., 51° 13′ W., was all that could be found, although visibility was good. The 26th was foggy, but on the 27th, 28th, 29th, 30th, and 31st the scouting in the cold water was continued with the idea of covering the ground thoroughly and definitely relocating the southern, western, and eastern limits of the ice.

On May 31 four large bergs were sighted close to the forty-ninth meridian between 42° 55′ N. and 43° 20′ N. One of these was a solid, massive, block of ice 115 feet high and about 400 feet square. Another large berg was seen in 43° 05′ N., 49° 29′ W. At daylight on June 1 visibility was not more than 3 miles, but it gradually increased during the day until shortly after noon it was 20 miles. The same five bergs were again sighted, although in much altered relative position due to varying currents. Dense fog prevailed on June 2 and the patrol vessel drifted.

On the morning of June 3 the fog cleared slowly. A search for ice was started to the southward, but none was seen. At 2.30 p. m. the *Tampa* relieved the *Modoc* in 42° 33′ N., 50° 20′ W.

In general, bergs continued to be unusually numerous north of the forty-fifth parallel. The only field ice heard of was that reported from north of the forty-eighth parallel by vessels on the "F" tracks. The surface water was unseasonably cold in many parts of the heavy ice area between the forty-fifth meridian and Newfoundland. The easternmost berg was reported on the 21st from 46° 50′ N., 40° 31′ W. South of the Tail of the Banks, where the *Modoc* worked most of the time, there was very little ice and the "B" tracks were not menaced.

Very few vessels reported crossing the eastern edge of the Banks between the forty-third and forty-seventh parallels. This is an important area, often called the gateway into the Atlantic for bergs. Water temperature, current, and ice conditions prevailing in it were not well known, but the patrol's duty to remain with the southernmost ice permitted but one excursion into it, and that into its extreme southern part only. Presumably very little ice was between the forty-fifth and forty-third parallels in the area concerned.

Eight oceanographic stations were taken in separated positions south of the forty-third parallel, the salinities of which were obtained at sea by the titration method without difficulty. No gales or even strong breezes were experienced on the fourth patrol cruise. Fog and visibility of less than 1 mile prevailed only 28 per cent of the time, but visibility was less than 4 miles 50 per cent of the time.

THE FIFTH CRUISE, "TAMPA," JUNE 3–18, 1929

Upon relieving the *Modoc* the *Tampa* immediately resumed the search between the Tail of the Banks and the "B" tracks to relocate the southernmost ice. On the 4th three bergs were found between

100277—30——2

the forty-ninth and fiftieth meridians, the southernmost being a large one in 42° 33′ N., 49° 48′ W. These bergs had been sighted by the *Modoc* on the 1st, when they were located some 40 miles to the northeastward. On the 5th the southernmost berg was left to run search courses westward. Three new bergs west of the fiftieth meridian were found, but as they were no closer to the "B" tracks than the large berg in the position mentioned above, they were left and the latter closely guarded until nearly noon on June 7. From the 4th to the 7th it remained in practically the same location, disintegrating steadily but rather slowly under the influence of 38° to 42° surface water. Very many ice reports were received from all over the patrol area during this time.

The *Tampa* stood to the southeast on the 7th because of the report of a very large berg in 41° 38′ N., 48° 56′ W. All of the 8th and parts of the 7th and 9th were spent searching the vicinity of this southernmost ice when visibility permitted. It could not be found, but a current setting southeast over 48 nautical miles per day was observed near its reported position. This was along the junction of 48° mixed water and 64° Gulf Stream water. The berg was probably carried to the southeast, then east, and finally northeast clear of the "B" tracks in this swift stream, for it was never sighted and it was not reported again after the 7th.

The afternoon of June 9 was spent running northwest toward the ice known to be south of the forty-third parallel. Ten bergs of this group were reported during the day by the *Tyrifjord* from near 42° 40′ N., 49° 10′ W. On the 10th the southernmost of these bergs was reached. It was the one first sighted by the *Modoc* nine days earlier and later watched by the *Tampa* until the 7th. It had remained in practically the same location for six days. The remainder of the 10th, a day of fine visibility, was spent searching to the northwestward. Four additional bergs were located near the Tail of the Banks.

On June 11 the *Tampa* cruised to the eastward near latitude 42° 40′ N. All five bergs sighted on the 10th were cut in by bearings as the vessel steamed along, as visibility remained excellent all morning. Seven additional bergs were sighted also, making a total of 25 known bergs south of 43° 10′ N. At 4.30 p. m. the patrol stopped in haze and rain near a berg in 42° 48′ N., 48° 51′ W. Nothing was seen on the 12th because of dense fog. On the 13th six bergs were sighted along the forty-third parallel between the forty-ninth meridian and the Tail. The 14th was foggy, but late on the morning of the 15th the fog cleared so that search for the southern limits of the ice could be resumed. Observations showed that during the thick weather the *Tampa* had been carried southwest past the Tail at the rate of about 1 knot by the current. One large berg was sighted on the 15th in 42° 17′ N., 49° 23′ W.

No ice was sighted on the 16th or 17th because of dense fog. The *Tampa* drifted on those days near the southernmost known berg waiting for clearing weather and the arrival of the *Modoc*. The bad visibility was widespread over the Labrador Current, cutting down the ice reports to practically nothing on the 17th. On the 18th, which was also foggy over large areas, the two cutters steamed slowly toward each other, sighting several bergs and growlers on the way.

Relief of patrol took place in dense fog at approximately 42° 40′ N., 50° 05′ W., at 5 p. m. on June 18. The weather was so thick that the annual surfboat race between the cutters could not be held until dusk, by which time a sufficient distance had been run to the southwest to get out of the fog area and into an area of good visibility over waters warmed by the Gulf Stream.

The fifth cruise was marked by the large number of bergs between the forty-second and forty-third parallels. They did not cross the westbound "B" tracks, but seemed to spread out east and west just south of the Tail between longitudes 48° 30′ W. and 52° 30′ W., keeping, except for the berg of the 7th reported from 41° 38′ N., well to the north of the warm Gulf Stream water and north of the forty-second parallel. Throughout the cruise occasional reports of ice came in from the few vessels crossing the ocean between the Tail of the Banks and Flemish Cap. This showed that there was still ice in the Labrador Current between 43° N. and 47° N. some of which could be expected to drift below the latitude of the Tail. Bergs were unusually numerous in the much traveled waters north of the forty-seventh parallel, but they were somewhat fewer there than during the previous patrol cruise, and they were on the average distinctly farther to the westward in the ocean.

The fifth cruise saw a general rise of sea temperatures throughout the ice patrol area; 34° water was not reported from anywhere to the patrol during the last 10 days of the period, but, even so, the surface temperatures in most localities averaged from 2° to 4° colder north of the forty-second parallel than on the corresponding dates in 1928. The oceanographic equipment worked excellently throughout the fifth cruise, 10 stations being occupied and computed.

On June 7 because of the number of bergs between 42° N. and 43° N., because of the southward push of cool mixed water down to 41° 30′ N., and because of the berg reported from 41° 38′ N., 48° 56′ W., the patrol recommended that traffic be shifted from tracks "B" to tracks "A" immediately. On June 12 word was received that "A" tracks were being put into effect.

The weather was extremely moderate throughout practically all the fifth cruise, only 6 hours of gales and 10 hours of strong breezes being experienced. At night and on cloudy days the unusually cold surface water caused some comparatively low air temperatures

to be noted. The dry bulb on the bridge frequently stood at 38° F., while the ship was cruising in the cold current near the Tail.

Four hundred and thirty-six reports of ice were received and twelve vessels were sent special ice information on request. There were, as usual, a number of reports of drifting buoys and spars. The isotherms on the fifth cruise chart are based on 150 observations of the patrol supplemented by just over 1,000 values sent in by 163 different cooperating vessels.

THE SIXTH CRUISE, "MODOC," JUNE 18–JULY 2

At daylight on June 19 the *Modoc* started searching toward the southeast for a berg reported the day before from 42° 10′ N., 48° 12′ W., but this berg could not be found although search was continued throughout the 20th for it.

The 21st, 22d, and 23d were spent searching northwestward to and past 43° 00′ N., 52° 00′ W. Excellent and at times phenomenal visibility prevailed. On the 23d the *Modoc* sighted 18 bergs to the southwest, west, and northwest of the Tail. When cooperating vessels reported six additional bergs south of the forty-third parallel on the 23d and 24th it was felt that every berg comprising the southern, western, and eastern limits of the ice at the time was located and known, for reporting vessels and the *Modoc* had thoroughly covered the entire critical area.

On the 24th courses were run to the southeast for a berg reported in 42° 00′ N., 50° 00′ W. A small berg 18 miles to the northeast of this position was sighted, but no large berg could be found. During the night the *Modoc* experienced a 2-knot current setting eastward in the warm water. The rapid and varying currents so frequently found along the junction of the Gulf Stream and the Labrador Current probably account for much of the difficulty experienced in trying to find bergs in the southeastern sector, even when the searches are based upon ice reports less than 24 hours old.

The 25th and 26th were devoted to searching in the southeast branch of the cold stream for the southeastern limits of the ice. No bergs were sighted. Due to fog patches that at times interfered with visibility, the search plans had to be frequently altered and occasionally the patrol had to drift until conditions improved. As the 27th was foggy a large part of the day, little could be done other than to retain position against the strong current setting eastward along the temperature wall. Few ice reports were received on the 26th and 27th on account of the fog. The 28th commenced foggy, but northwest breezes cleared the weather over the cool water before noon, permitting a large area along the forty-second parallel between the forty-eighth and fiftieth meridians to be covered before dark. Again no bergs were found.

On the 29th fog patches were once more in evidence and interfered seriously with the search for ice. One berg was sighted at 42° 26′ N., 50° 12′ W. During the afternoon the wind increased to a moderate east-southeast gale, with rain and low visibility. The *Modoc* was stopped just west of the Tail for the night and remained stopped there throughout the 30th due to fog.

On July 1 an attempt was made to examine the area over and just south of the Tail, but fog prevailed over the cold water. The fog still persisting at 3 p. m., the attempt to search the area just south of the Banks was given up and search of the warmer southwestern area was commenced. Considerable cruising was done on the 2d, but no bergs were sighted. The *Modoc* was relieved by the *Tampa* at 42° 55′ N., 52° 19′ W., at 12.30 p. m., on July 3.

During the sixth cruise bergs were reported in considerable numbers from near the Newfoundland coast in the vicinity of St. Johns. They extended farther southwest past Cape Race than on the previous patrol cruise. Bergs were still present in large numbers just north of the Grand Banks, where at least 125 different ones, many of them large, were reported from between the forty-seventh and fifty-second meridians. From along the eastern edge of the Grand Banks there were reported no less than 50 different bergs. Between corresponding dates in 1928 there was but one berg reported and none sighted along the eastern edge and no bergs were south of the Tail.

In the latitude of the Tail, where the *Modoc* cruised and made observations, there were numerous bergs between the forty-eighth and fifty-third meridians. More than three-fourths of the bergs to reach the forty-third parallel during the sixth cruise were curved to the west and northwest around the Tail in an extension of the Labrador Current. A number of bergs drifted south along the fiftieth meridian, however, and into the Gulf Stream influence noted previously to be flowing eastward strongly near the forty-second parallel. These bergs were carried southward to a limit near 42° 00′ N., 48° 00′ W., by tongue-like pushes of cool water that extended well into the Gulf Stream drift.

In the southern sector the *Modoc* saw that disintegration of the bergs went on rather rapidly under the influence of warm sun and warming surface water. The incoming temperature reports showed higher surface temperatures in all of the ice-patrol area than during the preceding cruise period. Besides the normal seasonal warming of the surface waters there was noted considerable encroachment of Gulf Stream water over areas that during the previous cruise were occupied by cool mixed water. As the end of the cruise approached it was apparent that great changes in the distribution of surface temperatures were taking place. Warm water had pushed northeastward

to the Tail, a very favorable condition for preventing any more bergs from curving around it and drifting to the west.

Seven oceanographic stations were taken. Accidental breaking of a glass carboy containing all the silver nitrate solution of the patrol prevented the immediate determination of the salinities of the water obtained, so the cases of water samples were taken to the *Tampa* for analysis in the electric salinometer on board that vessel.

Weather was again extremely moderate and seas were generally smooth. There were only four hours of winds of gale force and seven hours of strong breezes. Fog was recorded 23 per cent of the time, and visibility of less than 4 miles 39 per cent of the time.

Three hundred and seventy-two ice reports were received from ship and shore stations. Special ice information was sent on request to 10 vessels. The cruise isotherm chart is based on the observations of the *Modoc*, as supplemented by 829 temperature reports received by radio from 151 cooperating vessels.

THE SEVENTH CRUISE, "TAMPA," JULY 3–18

The region southwest of the Tail having just been well searched by the *Modoc*, the *Tampa* on taking up the ice-patrol duty on July 3 steamed eastward slowly through dense fog to a position from which to search south and east of the Tail as soon as visibility permitted.

The opportunity came the next morning and advantage was taken of the good weather by running under forced draft during all daylight hours on the 4th and 5th. The southeastern limits of water less than 50° F. at the surface were accurately determined, and the southeast sector was carefully searched for ice. Two small bergs and one large one were all that could be found south of the forty-third parallel and east of the fiftieth meridian. The warm water seemed to be crowding north rapidly, and very little water cooler than 60° F. at the surface was left south of the forty-second parallel.

Visibility being good at times on the 6th, the patrol was enabled to search north to the Tail and thence east along the forty-third parallel to the forty-ninth meridian. One berg in 55° water at 42° 24′ N., 49° 51′ W., was the only ice sighted. In view of steadily improving conditions existing in all parts of the patrol area, word was sent the Coast Guard headquarters that the steamship tracks could be safely shifted north from "A" to "B" lanes. The latter tracks began to be used on July 13. This recommendation, as will be seen later, proved premature, but at the time made it seemed thoroughly sound.

The 7th and 8th were days of very extensive dense fog, and the *Tampa* was forced to drift, waiting for good visibility before resuming the search for the southern limits of ice and cold water. No ice was either sighted or reported on the 7th. A few reports came

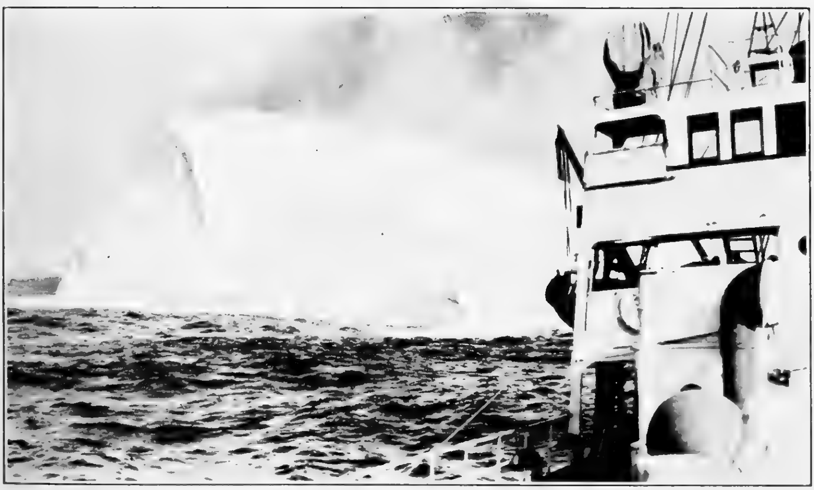

PLATE III.—The *Tampa* passing close to iceberg. In bright sunshiny weather the underwater ledges that project for short distances from some icebergs can usually be seen well enough to be avoided by a vessel moving at low speed

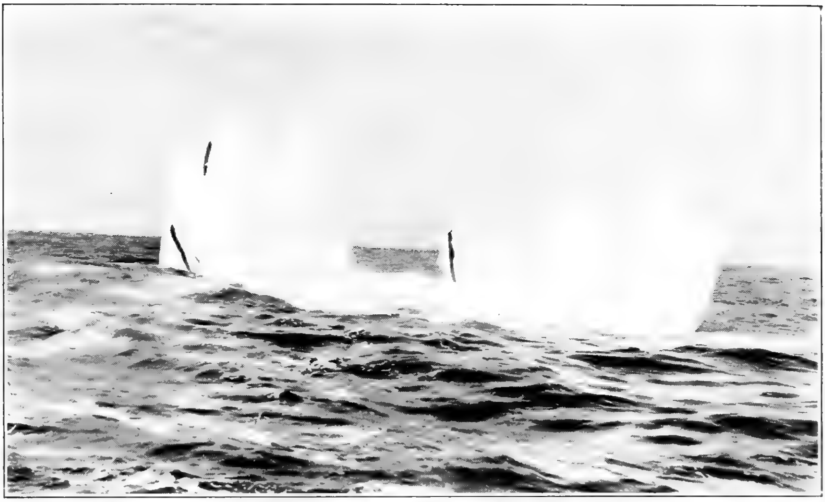

Plate IV.—An iceberg containing a layer of black dirt-impregnated ice. Taken from height of 18 feet on patrol ship, July 16, 1929, latitude 41° 46′ N., longitude 48° 50′ W.

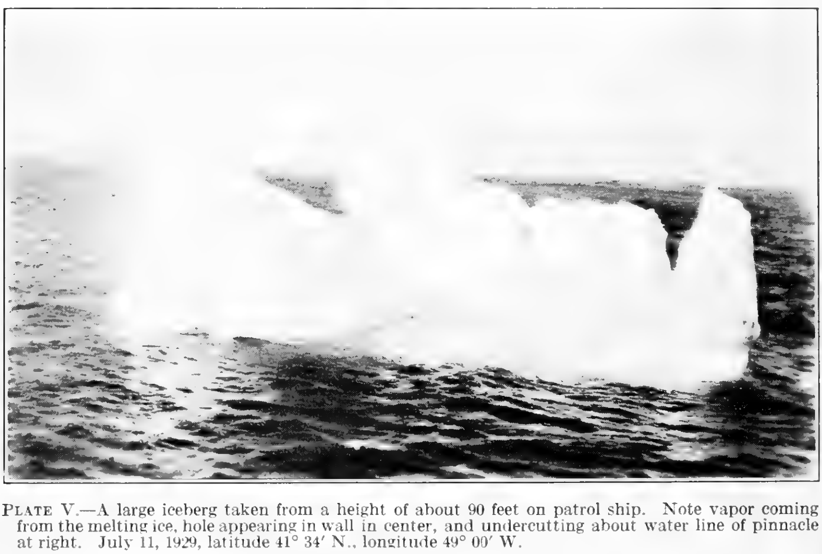

Plate V.—A large iceberg taken from a height of about 90 feet on patrol ship. Note vapor coming from the melting ice, hole appearing in wall in center, and undercutting about water line of pinnacle at right. July 11, 1929, latitude 41° 34′ N., longitude 49° 00′ W.

in on the 8th from north of the Banks, however, due to breaks in the fog blanket over that region.

The 9th was foggy until 2.30 p. m., when it cleared sufficiently to permit a search north to the forty-fourth parallel. Two bergs were sighted about 40 miles east of the Tail. The next morning while running south to search again in the southeast sector, these bergs were sighted a second time and were found to have drifted southwest at a 1-knot rate. This rather rapid drift was probably due to the fresh to strong northerly breezes which cleared up the weather having temporarily accelerated the flow of the Labrador Current along the eastern edge of the Banks.

Five more bergs were sighted before dark on the 10th. One was a small one in 42° 35′ N., 49° 52′ W. The other four were large ones just south of the forty-second parallel between the forty-ninth and fiftieth meridians. The southeasternmost ones were a pair of high dry-dock type bergs located in 41° 44′ N., 49° 00′ W. These bergs were watched on the 11th and 12th, but intermittent fog and overcast weather prevented the exact determination of their drift. As the bergs were in the narrow band of water between 50° and 56° F. at the surface, they were melting rapidly. From their thin walls vapor was curling in wisps.

On the afternoon of the 11th many tons of finely cracked ice were brought down into the sea from one of these bergs by means of eleven 6-pounder shells fired for experiment into pinnacles and vertical walls. On the 13th the only one of the bergs that remained in sight broke up into a larger and a smaller part. By noon the sights showed that the larger piece was drifting rapidly north away from the "B" tracks. Accordingly, it was left for a more southerly report of ice from 42° 03′ N., 48° 41′ W. This last ice, though less than 20 miles away, was not moving northeast, but was in a south-setting eddy. On the morning of the 14th a small and a large growler, all that remained of it, was in 41° 44′ N., 48° 44′ W. This ice was left before noon for a large berg reported in 41° 34′ N., 48° 11′ W. A small smooth berg found very close to this last position was watched the remainder of the day. It rolled about frequently in melting and gave off vapor continually to the damp air.

On the 15th two bergs reported from farther to the west were approached. They were found in 41° 34′ N., 48° 58′ W. in 56° surface water, and, proving to be large ones, were closely watched throughout the 15th. Their drift was 80° true at the rate of about 1 knot. During the day several steamers passed on the westbound "B" tracks within sight of the patrol and the bergs. Conditions had materially changed for the worse since these tracks were recommended 9 days earlier, the southernmost ice being now practically on the new lanes.

The 16th was spent watching the same two bergs as they continued to move northeastward away from the tracks. By the morning of the 17th they were drifting a little south of east, however, being at 6.30 a. m. near 41° 45′ N., 48° 35′ W. The smaller of the two, marked by a layer of dirty black ice, was by this time much reduced in size and so much cut up by wave action as to be ready to break up into three pieces at any time. At 7.40 a. m. course was set for a large berg with growlers reported from 42° 07′ N., 50° 11′ W. Visibility was excellent, but no unreported ice was sighted on the way. The berg proved to be a very large, solid one over 125 feet high, floating in 58° surface water. From this berg westerly courses were steered to a rendezvous with the *Modoc* in 42° 00′ N., 52° 00′ W., near which position relief of patrol was effected at 1 a. m. on July 18, 1929.

Bergs did not curve around the Tail to the westward during the seventh cruise as they did during earlier ones. The ice, blocked from the southwest sector by a warm tongue, was carried by a push of cold water between the forty-eighth and fiftieth meridians farther south than at any other time during the year. Two or three different bergs were reported as south of 41° 30′ N. and six or eight different bergs drifted below the forty-second parallel. Throughout most of the seventh cruise the *Tampa* guarded these southeastern bergs and watched their disintegration.

There were about 20 bergs reported from along the eastern edge of the Banks and 60 from along the "F" tracks north of the Banks between 47° west and Cape Race. This was an unseasonably large number, but nevertheless it marked a considerable falling off as compared with the sixth cruise. The number of different bergs south of the forty-eighth parallel during the seventh cruise was only about half that during the sixth cruise, while the sixth cruise recorded about half as many as the fifth. It was evident that the ice was melting at higher and higher latitudes and that the arrival of the date when bergs would no longer be a menace to the "B" tracks would only be a matter of a short time.

The salinities of water samples from the seven stations taken on the *Modoc* were determined in the salinometer on the first two days of the *Tampa's* cruise. Nine oceanographic stations were taken on the seventh cruise, usually near bergs after the vessel was through cruising for the day. These salinities were determined also and all the stations were worked out before the *Modoc* was met on July 18. The oceanographic apparatus worked well. It was found that the warmth in the Labrador Current was confined to the surface layers. Even south of the forty-second parallel where the water was 56° to 64° F. at the surface, 37° and 38° water at the 125-meter level was found at all stations. Farther north the cold water was encountered

closer to the surface, sometimes at the 25-meter level and sometimes at the 50.

Winds of gale force were entirely absent during the seventh cruise and there were but two hours of strong breezes, the period being marked by fine moderate weather as a rule. On July 9 and 10 air temperatures of 44° and 43° F. were recorded while cruising in the 44° and 43° surface water to the east and northeast of the Tail. Throughout the greater part of the cruise air temperatures were in the 50's and 60's, however. Fog prevailed 29 per cent of the time and visibility of less than 4 miles 34 per cent of the time.

During the seventh cruise 131 ice reports were received from ship and shore stations. Eight vessels were sent special ice information on request. Eighty-four different vessels sent in 670 water temperature reports, which were invaluable for use in supplementing the *Tampa's* own records. The combined observations permitted an excellent idea of the distribution of Gulf Stream and Labrador Current water to be had.

THE EIGHTH CRUISE, "MODOC," JULY 18–AUGUST 1

When the *Modoc* relieved the *Tampa* on July 18 southwest of the Tail courses were laid to the eastward to examine bergs threatening the tracks between the forty-eighth and fiftieth meridians. Before dark, a medium-sized berg was sighted at 42° 28′ N., 50° 05′ W., and a larger berg of at least 500,000 tons mass at 42° 03′ N., 49° 31′ W. The latter was the one sighted by the *Tampa* on the 17th about 10 miles to the westward. The night was spent in 61° surface water near this big berg. During the hours of darkness it must have calved heavily, for it was surrounded by growlers and small pieces when it was left early on the 19th for the southeasternmost ice.

Only one of the two reported southeastern bergs was found by the *Modoc* on the 19th, and on the morning of the 20th a growler was all that remained of the one found. At 2.45 p. m. it was no longer a menace to navigation and was left for a small berg reported in 41° 09′ N., 48° 43′ W., about 60 miles to the southward. Systematic search failed to reveal this southernmost berg of the year. It probably melted quickly in the 56° to 60° surface water of the vicinity, for it was not reported again.

On the 22d, a northwesterly course was run for the British tanker *Vimeira*, of Glasgow. That vessel had struck a berg and become disabled in 42° 40′ N., 49° 44′ W., about 135 miles north of the eastbound "B" tracks, then in effect. She was reached at 5.30 p. m. and boarded. The master stated that while making 11.5 knots on an easterly course at 11.50 p. m. on July 20 his ship ran suddenly out of clear weather with bright moonlight and into a fog bank. Before speed could be reduced or he could be called she struck with

her port bow a berg that was in the fog. The berg scraped aft along the port side and bent one of the propeller blades to such an extent that the screw could not be turned over. The stem was bent and the port bow stove in from the forecastle deck to well below the water line. Only the forepeak tank was flooded, however, and the vessel was in no danger, either immediate or prospective. Many tons of ice from the berg had been forced into the forecastle through the openings made between the plates. Fortunately, the watches were being changed when the collision occurred and the bunks inside the portion of the bow that was damaged were unoccupied at the time; therefore, no person was injured.

Before the *Modoc* departed to return to the southernmost ice the master of the *Vimeira* had made arrangements by radio with the steamship *Olna* for a tow to Halifax, Nova Scotia. When the patrol vessel left the scene the berg that had caused the damage was still in sight on the horizon to the southwest.

The *Vimeira* on previous trips this year had crossed the ice-patrol area well to the southward of the Grand Banks to avoid bergs. During this last trip also she received the ice-patrol broadcasts regularly. The broadcast on the evening on which the vessel struck the berg reported a berg as on the 16th in 43° 51′ N., 49° 15′ W., and also reported a large berg as on the 17th in 43° 35′ N., 49° 14′ W., which the message stated, had probably drifted south-southwest. In all probability these two reports were on the same berg. As bergs often drift to the southward along the eastern edge of the Grand Banks at the rate of about 20 miles per day, the probable latitude of the berg on the 20th was 42° 40′ N., and it is likely that the berg struck by the *Vimeira* was the one that was on the 17th in 43° 35′ N., 49° 14′ W. The master doubtless plotted the positions of all the southernmost bergs reported in the broadcast and, noting an apparent clear space on his chart, shaped course through it. Masters should note the date of all ice reports in the broadcasts and give careful consideration to the date as well as the position of reported bergs in shaping course across the ice regions. To be certain of clearing all reported bergs due allowance must be made for their possible drifts.

On the 23d, at 7 a. m., the berg of the 17th and 18th was passed in 42° 10′ N., 49° 30′ W., still in approximately the same location as on the 17th. It had decreased considerably in size since last seen. By 9 a. m. a small berg about 30 feet high in 41° 49′ N., 49° 20′ W., the southernmost known ice, was reached. As search to the southward and westward for more ice proved unsuccessful, the patrol vessel returned to this berg late in the afternoon, finding it diminished to about 15 feet in height. When left on the morning of the 24th it was a small growler not over 3 feet high, the last trace of which must have disappeared early in the afternoon.

The berg of the 17th and 18th, being the southernmost ice remaining, was closely watched from the 24th to the 26th. On the afternoon of the 24th it calved heavily. On the 26th a few growlers were all that remained of the berg and these melted entirely shortly after dark.

The 27th and 28th were spent searching to the north for the new southern limit of the ice. The area between the forty-ninth and fifty-first meridians was covered as far as the forty-third parallel by nightfall on the 28th, but no ice was seen. The 29th, 30th, and 31st, days of dense fog, were spent just off the eastern edge of the Banks in a position to continue search northward up the cold current should good seeing weather return.

August 1 was spent running to the westward toward the *Tampa*. As soon as the warm water west of the 50-fathom curve of the Banks was reached the fog was left behind. The *Tampa* was met at 2 a. m. on August 2 in 43° 00′ N., 51° 30′ W., where the relief of patrol was effected.

Ten stations were taken during the eighth cruise. As there remained no means for determining sea-water salinity on board, the water samples were saved for analysis on the *Tampa*. Sustained winds of gale force and strong breezes were absent during the eighth cruise, which was marked by fine moderate weather. There were some sharp rain squalls, with lightning and wind, over the warm water and much fog over the cool water farther north. Fog was experienced 34 per cent of the time and visibility was less than 4 miles 46 per cent of the time.

During the eighth cruise 67 ice reports were received from ship and shore stations. Seven vessels were sent special ice information on request. Eighty-nine different coöperating vessels sent in 651 sea-water temperature reports. The isotherm chart based on these values and those obtained by the *Modoc* shows continued slow general solar warming of the surface layers. In the vicinity of 41° 00′ N., 49° 00′ W., there was a push of cold water farther south than during the last cruise, but upon the melting of the southernmost bergs the possible supply of ice for this area was cut off.

During the eighth cruise the 1929 ice menace to the Europe-United States "B" tracks definitely appeared to end. After the melting of the four bergs that were south of the forty-second parallel during the first half of the cruise the ice limits retreated steadily northward. As berg after berg of the southernmost ones melted in the summer air and sea temperatures prevailing, they failed to be replaced from the north due to lack of supply in that quarter and to probable weakening and narrowing of the Labrador Current. Persistent fog over the cold water blocked effective searching during much of the latter part of the eighth patrol period, however, and prevented a thorough clearing up of the ice situation or a definite recommendation regarding the discontinuance of the patrol.

THE NINTH CRUISE, "TAMPA," AUGUST 2–4

Upon relieving the patrol on August 2 the *Tampa* instituted a final search for the southernmost ice. By 10 a. m. the southern end of the cold current with surface temperatures between 55° and 58° F. just southeast of the Tail was entered. It was found to be but 20 miles wide, being bounded on the west, south, and east by water 60° and higher in temperature. Good visibility prevailed until the search had been carried north along the eastern edge of the Banks to 43° 30′ N. Here 52° water covered with a low fog was met. At 7 p. m. on the 2d the *Tampa* was stopped for the night in 43° 42′ N., 49° 05′ W.

The *Modoc* had watched all the bergs south of the forty-third parallel break up during the previous cruise, and only two other bergs south of the forty-eighth parallel had been reported since July 22. The more southern of these was in 44° 52′ N., 48° 34′ W., on July 27. When no ice was found in the cold water south of 43° 30′ N. by the patrol it became evident that this berg had either melted or drifted off to the northeast. It seemed a practical certainty that the ice menace for the 1929 season was absolutely over so far as the "B" tracks were concerned, and fairly certain that no more bergs could get south of the forty-third parallel before the spring of 1930. Accordingly, a message summarizing the situation and recommending the discontinuance of patrol was transmitted to headquarters on the evening of August 2.

On the 3d a southwesterly course was run across the Tail. Fine visibility prevailed over the shoal water, which was warmed to from 60° to 64° at the surface, but fog continued over the cold stream off the eastern edge. On the afternoon of the 3d, when information was received that the 1929 international ice patrol was discontinued, a course was laid for Boston, Mass. The last broadcasts of the season were transmitted on the evening of the 3d and on the morning of the 4th. They contained a notice of appreciation for the valuable assistance in the way of reports received from shipping. Port was reached without incident, and the *Tampa* moored at the Boston Navy Yard at noon on August 6, 1929, thus ending the longest ice-patrol season on record.

One oceanographic station was occupied during the ninth cruise. The water from it and from the 10 stations last taken on the *Modoc* was run through the salinometer before noon on the 4th and all stations were computed before Boston was reached. The isotherms on the cruise chart for the short ninth cruise are based on 148 values sent in by 16 different vessels and on 102 readings taken from the log of the *Tampa*. The curves show some continuation of warming in the surface layers. There was only one ice report received; one vessel given special ice information.

During the ninth cruise southwesterly breezes prevailed in the ice-patrol area, making the weather damp and muggy over the 55° to 65° water and persistently foggy over the 50° to 55° water. There were no gales, but the patrol before reaching Boston experienced some strong breezes due to the influence of two disturbances whose centers traveled across the Gulf of St. Lawrence.

RADIO COMMUNICATIONS

The radio apparatus used on the *Tampa* and the *Modoc* during the 1929 ice-patrol season was practically the same as that used by the patrol vessels during the 1927 and 1928 seasons. The main changes on each ship were the substitution of improved receivers for older types. Each ship in 1929 had for transmitting purposes one T–2 2-kilowatt tube transmitter, using either CW or ICW or phone transmission; one T–4 200-watt tube transmitter using either CW or ICW transmission; and one 500-watt XA crystal-control high-frequency transmitter. The latter type of set was very useful for clearing at scheduled times a large volume of direct traffic with NAA, the United States naval radio station near Washington, D. C. The distance between the patrol vessel on duty and that station averaged about 1,350 sea-miles.

The receiving apparatus on each ship consisted of one special high-frequency screen-grid receiver, type CGR–24, and one low-frequency receiver, type CGR–25, also screen grid. These receivers were recently manufactured for the United States Coast Guard and were the most up-to-date instruments in the service, being a big improvement over old types. They gave very satisfactory results on ice-patrol work. The 1929 receiving equipment included, in addition, the latest type direction finder or radio compass, which was invaluable for making quick and sure contact with the vessel coming out to relieve the patrol. Each vessel had also one CGR–1 receiver for use on the Coast Guard frequency band.

During the season there were no serious breakdowns of either sending or receiving sets. Free use of the good supply of spare parts and immediate rectification of all small troubles that developed combined to keep all apparatus in the radio department close to perfect operating condition at practically all times.

Normally United States Coast Guard cutters of the *Tampa* class carry four radiomen. While on ice-patrol duty this year, however, each patrol vessel carried in addition one radio electrician. This policy provided the services of an experienced supervisor on each vessel, which proved to be of great benefit, for the year 1929 had not only the longest ice-patrol season to date, but also, from a communications standpoint, by far the most arduous one on record. Due to extreme heaviness of schedule traffic, to the great number of ice

reports coming in between schedules, and to the increase in number and activity of vessels cooperating by sending in water temperatures and weather reports, the radio department was far busier in 1929 than ever before.

The figures given below indicate how the communication work of 1929 compared with that of 1928 which was a good average ice year, and, due to increasing cooperation from passing steamers, the former record year for total volume of radio traffic.

	1928	1929
Routine broadcasts transmitted	760	984
(Broadcasts averaged about 300 words each in 1928 and about 400 each in 1929.)		
Water temperature and weather reports sent in by cooperating vessels	6,534	7,225
Total number of cooperating vessels	489	539
Number of ice and obstruction reports received by radio	644	2,255
Total number of words transmitted and received by radio	450,460	807,737

The following tabulation shows the times when the most important special ice-patrol traffic schedules were kept. The times given, which are all in Greenwich mean civil times, will doubtless be used during the 1930 season also, though there may be some slight changes necessary to make them fit in with prevailing traffic conditions at the various shore stations.

Time — Remarks

0000. Radiobroadcast to shipping on 175 kilocycles.

0030. To Hydrographic Office, Washington, giving latest ice news, followed by report to Weather Bureau, Washington, giving meteorological information.

0100. Schedule with naval radio station at Bar Harbor, Me.

0230. Receive from NAA, near Washington, D. C., traffic on hand for ice patrol.

1100. Radiobroadcast to shipping on 425 kilocycles.

1148. Report to Weather Bureau, Washington, giving meteorological information.

1200. Radiobroadcast to shipping on 175 kilocycles.

1300. Schedule with naval radio station at Bar Harbor, Me.

2300. Radiobroadcast to shipping on 425 kilocycles.

SUMMARY REPORT OF THE COMMANDER, INTERNATIONAL ICE PATROL

Commander Thomas M. Molloy

The *Tampa* left Boston, Mass., on April 1, to inaugurate the 1929 ice patrol. The *Tampa* and the *Modoc* each spent four full 15-day periods in the ice regions during the season. The patrol was discontinued at word received from Coast Guard Headquarters on August 3, when the *Tampa* was on the second day of the ninth patrol period. Halifax, Nova Scotia, was used as a base for fuel and supplies, as in previous years. During the season the two patrol vessels cruised a total of 23,249 nautical miles, which figure includes the distance run while going to and from the base.

The weather, as is usually the case, was raw and boisterous the first patrol cruise, but it steadily improved as the season progressed, so that during the last half of May and all of June there were but nine hours of gales. During the last month of the patrol season unusually moderate conditions prevailed, there being no gales whatever. The normal large amount of Grand Banks fog was experienced. The full season was about equally divided in point of time by foggy, clear, and overcast weather conditions.

Sixty-nine oceanographic stations were occupied during the season from time to time as opportunity offered. The salinities of the water samples were all determined on board ship and the dynamic computations were all worked out before the end of the active season. If the work of ice scouting and trailing had permitted the station work would have been more extensive and systematic. As it was, unprecedentedly heavy ice conditions required the patrol to concentrate on the practical work of watching the southernmost ice and on the service of information rather than on a comprehensive oceanographical program. Frequent soundings were taken with the fathometers, the results being tabulated for future correction and hydrographic use whenever the ship's position was well fixed by observations.

Ice was rather late in appearing in the Atlantic off the Grand Banks in 1929, and April 1, when the first vessel departed on patrol, marked a later starting of the active season than in any year since 1920, when the first vessel left New York on April 3. Because of the heaviness and persistence of the ice once it began to come down, however, the season proved an extremely long one, lasting 128 days. Word to discontinue the 1929 patrol was not received until August 3, a full

20 days later than the same word was received in 1925. Until this season 1925 had been the record year for late continuance of patrol.

Very early in the season it became evident to the patrol that the ice year was an unusual one. On the first cruise, April 1 to 19, numerous bergs were sighted and reported off the eastern edge of the Grand Banks between the forty-fifth and forty-second parallels as was to be expected, but north of 45° reports showed that ice conditions were extremely bad. One vessel that tried to use the Cape Race tracks westbound early in April was forced to skirt the edge of field ice and bergs southward for 250 miles near the forty-eighth meridian. She reported from the northern sectors "solid packed bergs and growlers extending as far as can be seen to the north, west, south, and southeast."

In view of the extremely heavy field ice and berg conditions prevailing between the forty-seventh and fiftieth meridians, the shifting north of the Canadian routes from "D" to "E" on the regular date, April 10, seemed very inadvisable to the patrol. Conditions were so bad along the "E" tracks when they were put into effect that many vessels for weeks did not try to force passage on them, but detoured to the south 80 to 100 miles so as to pass around the southern end of the field ice of the Labrador Current.

From April 20 to June 1 the field ice retreated until it was all north of the forty-ninth parallel and no longer being reported to the patrol. The bergs, however, remained in enormous numbers. They did not gain any extreme southerly positions, as nearly all of them that reached the forty-third parallel were curved to the westward around the Tail of the Banks. During June the bergs south of latitude 48° N., though still above normal in numbers, began to thin out. It is impossible to give exact figures of the numbers of bergs in any year because of great duplication of reports from near the Canadian tracks and of scarcity of reports of ice from other areas. Taking all known factors into consideration, however, it is always possible to make very fair estimates. In 1929 it is estimated that there were 460 different bergs south of the forty-eighth parallel during May and 376 different bergs during June. When it is realized that 386 bergs constitute the average number to drift south of the forth-eighth parallel during the whole of a normal ice year the severity of the 1929 season from an ice standpoint is at once apparent.

Throughout the season it was noted that the surface water was 2° or more colder than average for the date in most of the ice-patrol area north of the forty-second parallel. The amount of water just in the wave-mixed surface layers of the area concerned is so great that it is hardly conceivable that even the large number of icebergs which drifted south of the forty-eighth parallel chilled the water measurably in melting. The probabilities are that the reason for

much ice and colder water than usual in the northern half of the ice-patrol area must be searched for in some combination of causes operating to produce an unusual outpouring from the far north. The discharged waters were probably only incidentally studded with icebergs in the Grand Banks region, where, conserved by the cold water and protected against attrition by strength of numbers, they persisted to a very late date and, as mentioned above, kept the patrol in effect longer than ever before.

During June the southern part of the Labrador Current, instead of flowing westward around the Tail, as it did earlier, was split into two main branches. One of these continued to flow westward around the Tail and carried large icebergs to 43° 00′ N., 53° 00′ W., but the other branch flowed strongly southeast to 40° 00′ N., 47° 00′ W. During July the western branch noted above was wiped out and practically all the ice that got below the Tail was taken charge of by the southeast flowing stream. At least eight different bergs were carried in the latter circulation south of the forty-second parallel and close to the westbound "B" tracks during the month. The last of these bergs melted to nothing under the eyes of the patrol on July 22, and on the 26th of July the last ice south of the forty-third parallel was also observed to melt. By the latter date bergs were very sparse south of the forty-eighth parallel on account of their melting in higher and higher latitudes due to the advancing summer conditions and also to the probable shrinking and weakening of the Labrador Current.

All the bergs that were watched during the latter part of the season broke up rapidly. To illustrate the rate at which bergs can melt in warm water the case of a large berg of at least 500,000 tons mass can be given. It was first seen near 42° 00′ N., 49° 00′ W., in 61° water on July 17. In just nine days the last traces of it were closely watched as they disappeared. Such rapid disintegration is not caused by melting alone, but is greatly speeded up by frequent calving, sluffing, and division.

By the evening of August 2 it was decided that the ice menace for the "B" tracks was definitely over, and recommendation for the discontinuance of the patrol was sent to Coast Guard headquarters. This recommendation could probably have been made four or five days earlier if the ice patrol's worst enemy—fog—had not effectively and continuously blanketed nearly all the critical cold-water regions during the last week of the patrol. Permission to discontinue the patrol was received on the afternoon of August 3 and the *Tampa* reached Boston, Mass., just before noon on August 6.

It should be kept in mind that radio communication is the one thing that is of utmost value to the patrol. Without radio practically no late information could be given out and comparatively little could be gathered. In spite of the great volume of traffic caused by the un-

usually long and heavy ice season, the radio apparatus and personnel stood up excellently. Every effort is made before the season starts to see that all radio equipment is ready for the strain that will come upon it and to have the latest improvements for the sets installed. The magnitude and importance of the communication work of the patrol can be grasped in part by a study of the figures relating to volume of traffic shown on page 26 of this pamphlet.

On the night of July 20 the British tanker *Vimiera* struck a berg at 42° 40′ N., 49° 44′ W., some 70 miles north of the westbound "B" tracks, which were then in effect for passenger vessels. She was badly stove in forward and her propeller was totally disabled by the bending aft of one of its blades as the ship scraped by the berg. Fortunately, there was no loss of life or even injury to anyone. Her case should serve as a warning to the masters of other vessels to proceed cautiously when in the ice regions during all times of low visibility. Recent comparative freedom from disaster seems to be causing a growing carelessness, for the patrol noted in 1929 no less than 100 cases of failure on the part of passenger vessels to adhere to the tracks prescribed by the trans-Atlantic track agreement. Every ship that crosses the iceberg area at a speed greater that that at which she can either turn or stop before striking a berg seen ahead under the conditions of visibility prevailing is playing a game of chance.

Thanks particularly to improved radio and to more effective coöperation from shipmasters, much progress has been made during the past 14 years, and it is believed that a more efficient patrol can be maintained now than then, but it must not be thought for an instant that the ice patrol is infallible or that it is all-seeing. Broadcasts listing the positions of all the southernmost ice of which the patrol has knowledge are regularly sent out, but shipmasters must always realize that ice can move rapidly and seemingly erratically when it is off the eastern edge of the Grand Banks and still faster and more incomprehensibly when it is south of latitude 43° N. The dates given with all berg positions in the broadcasts show the freshness of the several reports. Possible drifts since time of report must be considered by shipmasters most carefully.

In view of the increasing speed and importance of trans-Atlantic travel, this summary of the 1929 ice-patrol season can not end better than by sounding a final warning by means of the words with which Capt. F. A. Levis, of the *Seneca*, closed his summary of the 1915 ice-patrol season. These words are as true now as they ever were and they will in all probability always remain true. Captain Levis said: "*Of course there is always a chance that a berg will reach the steamer tracks without being seen or reported, on account of prolonged periods of fog,* but the presence of the ice-patrol vessels near the danger zone assures passing vessels that assistance is near by in case of disaster."

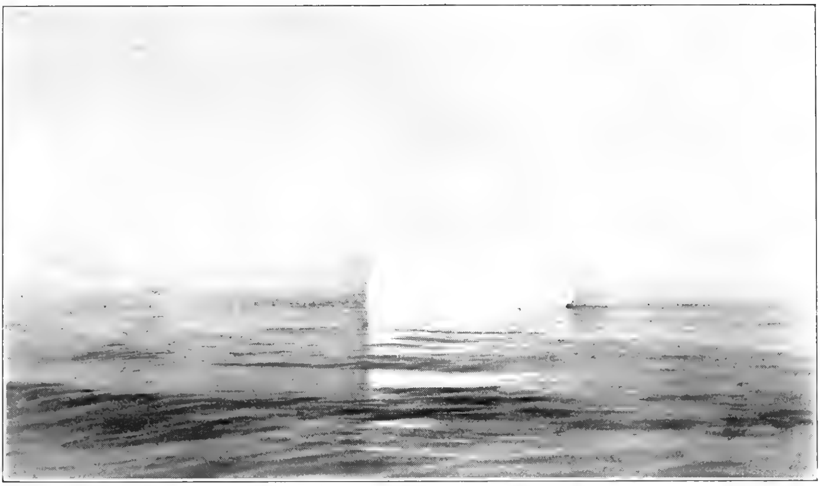

PLATE VI.—A tabular iceberg such as is frequently seen north of the forty-third parallel. This sort of berg is usually very stable

PLATE VII.—A tabular iceberg nearing its end as such. The flat surface which was: ormerly the top is being slowly submerged, and the wave-cut terrace at the left is being slowly elevated due to the particular manner in which the underwater body is melting

PLATE VIII.—A Greene-Bigelow water bottle clamped to the sounding wire. Seven such metal bottles are clamped on at different points and lowered into the sea at each oceanographic station. The upper bottle is tripped when a messenger is slid down the wire. In tripping, a messenger is released from the bottom of the bottle to slide down to the next one in the series, and so on

PLATE IX.—Reading the reversing thermometers in a Greene-Bigelow water bottle that has been tripped on the wire at a known depth and then hoisted up and taken aboard. The cylinder fitted with two pet cocks contains over a quart of sea water from the level at which the bottle was tripped

TABLE OF ICE AND OTHER OBSTRUCTIONS, 1929

Date	No.	Reported by —	Position: Latitude north	Position: Longitude west	Nature of ice or obstruction
			° ′	° ′	
Jan. 11	1	Cape Race Station	50 38	45 36	Berg.
24	2	do	45 28 to 45 23	59 18 to 58 08	Field ice.
25	3	do	45 00 to 45 10	59 15 to 58 20	Scattered field ice.
26	4	do	45 06 to 44 58	58 27 to 59 22	Loose field ice.
26	5	do	44 24	61 20	Slob ice.
28	6	do	45 09	59 26	Field ice in band 4 miles wide stretching north and south.
Feb. 1	7	do	45 30 to 44 45	59 10 to 60 20	Field ice covering large area.
2	8	do	44 56	60 20	Field ice.
6	9	do	44 40 to 44 45	60 37 to 59 35	Pancake ice.
14	10	do	48 11	49 50	Sludge ice.
14	11	do	44 45	59 50	Field ice.
17	12	do	47 45	51 05	Growlers extending northward.
17	13	do	44 41 to 44 39	59 49 to 60 06	Heavy field ice.
18	14	do	47 45 to 47 45	52 30 to 51 30	Light open field ice.
20	15	do	47 16 to 47 35	51 57 to 51 20	Open field ice.
20	16	do	47 35 to 47 58	51 20 to 50 43	Sludge ice.
25	17	do	47 00	52 30	Slush ice.
26	18	do	47 25 to 47 52	51 30 to 50 45	Heavy field ice.
26	19	do	48 30	49 30	Field ice.
27	20	do	46 45	51 10	Heavy field ice.
27	21	Drottningholm	47 01 to 47 07	50 01 to 49 01	Heavy patches field ice and numerous growlers.
27	22	Arnold Maersk	48 08 to 46 50	48 50 to 51 20	Heavy to light field ice.
28	23	Cape Race Station	47 02 to 46 25	47 50 to 47 40	Drift ice and growler.
Mar. 1	24	Gripsholm	45 53	47 54	Scattered growlers.
5	25	Vela	48 00	51 35	Close field ice.
10	26	Wytheville	47 14	47 34	Small growlers.
10	27	do	47 09	47 54	Large growler.
11	28	Cape Race Station	48 48 to 48 25	48 18 to 48 20	Large growlers and small pieces of ice.
11	29	do	48 25	48 20	Small berg and growlers.
11	30	do	48 04	48 12	Small berg, large growlers.
11	31	do	46 59	47 56	Small growler.
11	32	do	47 04	48 33	Small berg.
11	33	do	47 20	47 30	2 large growlers.
11	34	do	47 25	47 20	Small growler.
14	35	do	47 54 to 47 25	47 02 to 47 21	Heavy field ice, numerous growlers.
1	36	do	49 03	50 04	Heavy field ice and growlers.
2	37	do	44 35	48 34	Several growlers.
3	38	do	45 45	47 46	Several small growlers.
5	39	do	45 30	48 10	Scattered growlers.
5	40	do	47 10	49 30	Very heavy field ice.
6	41	do	45 41 to 46 10	48 46 to 47 50	Several growlers, small ice.
7	42	do	48 43	50 00	Large growlers and small ice.
8	43	do	48 43 to 47 20	50 00 to 51 40	Do.

Table of ice and other obstructions, 1929—Continued

Date	No.	Reported by—	Position		Nature of ice or obstruction

			° ′	° ′	
Mar. 10	44	Cape Race Station	47 13	48 36	Small growlers.
10	45	do	47 09	47 54	Large growler.
11	46	do	48 04	48 33	Small berg.
14	47	do	47 54 to 47 25	47 02 to 47 21	Heavy field ice, numerous growlers.
15	48	do	46 46 to 46 44	50 27 to 51 15	Heavy field ice.
16	49	Ernst Hugo Stinnes II	47 43	44 53	4 bergs with drift ice.
17	50	Lituania	48 25 to 46 39	49 51 to 52 52	Several small bergs, numerous growlers, field ice.
17	51	do	45 18	58 09	Loose field ice.
17	52	Cape Race Station	48 44 to 48 05	48 55 to 50 40	Heavy field ice, numerous growlers, and bergs.
17	53	do	46 16 to 46 10	47 38 to 48 10	Field of ice consisting of numerous growlers surrounded by heavy packed ice.
17	54	do	46 10	48 12	Low berg.
22	55	do	48 04	48 11	Small berg.
22	56	do	48 57	48 16	Small bergs.
22	57	do	48 01	48 18	Do.
22	58	do	48 02	48 21	Large growlers.
22	59	do	48 03	48 27	Small berg.
22	60	do	48 04	48 25	Small berg, open drift ice, growlers.
23	61	do	48 04 to 47 45	48 11 to 48 38	Belts of drift ice with bergs and growlers.
23	62	do	48 06	47 20	Small berg.
23	63	do	46 30	47 04	Growlers and small pieces of ice to the northwest.
23	63a	do	46 08	48 20	Small berg.
23	64	do	46 30	47 04	Growlers and small ice to northwest.
28	65	do	46 15	46 18	Large berg, small ice.
28	66	do	45 45 to 45 16	47 07 to 48 20	Several bergs, belts of field ice.
28	67	do	45 15	48 30	2 bergs.
28	68	do	46 10 to 45 30	46 30 to 47 20	Large ice field, high bergs.
28	69	do	46 15	46 18	Berg, same as 65.
28	70	do	44 54 to 44 48	58 15 to 57 20	Heavy field ice to northward.
23	71	Estonia	48 04 to 47 45	48 11 to 48 38	Belts of drift ice, small bergs, and growlers.
29	72	Cape Race Station	46 10	46 08	Berg, same as 65.
30	73	do	46 55	46 14	Heavy field ice, growlers, and bergs.
30	74	do	46 39	46 39	Berg.
30	75	do	46 30	47 27	Do.
30	76	do	46 00	47 20	Do.
30	77	do	44 40 to 44 30	48 53 to 49 15	Heavy drift ice, growlers, and 2 bergs.
31	78	do	44 30	49 00	Soft field ice with some large pieces.
31	79	do	44 46	58 18	Large patches field ice to north and northeast.
Apr. 1	80	do	46 05 to 45 08	48 18 to 48 30	Heavy field ice, numerous bergs.
1	81	do	46 04 to 47 00	50 36 to 48 45	Do.
1	82	do	43 22	49 07	Several growlers.
2	83	do	43 19	49 05	Large growlers, small bergs, small pieces.
2	84	do	43 38	48 50	Several small growlers.
2	85	do	43 10	49 00	2 small bergs, broken ice, growlers.
2	86	do	47 00 to 47 23	48 45 to 47 43	Large fields drift ice, scattered growlers, several bergs.
3	87	Hellig Olaf	45 57	47 58	Small berg and several pieces of ice.
3	88	Eastern Dawn	42 59	49 21	Large berg, several growlers.
3	89	do	43 06	49 00	Berg.
3	90	Cape Race Station	40 09	48 15	Large piece wreckage.

WEATHER

Throughout the 1929 ice-patrol season the vessels actually on patrol remained within 120 nautical miles of 42° 30′ N., 49° 30′ W. That position, therefore, can be taken for all practical purposes as the place where the observations, which are described below, month by month, were made. But too much stress should not be placed on this position, for the weather experienced by the ice-patrol vessels depends to a very great extent on their location in the ice-patrol area. The northern part of the area cruised in is often cold and foggy because of Labrador Current water, while, at the same time, the near-by southern part of the ice-patrol area is warm and sunny because of Gulf Stream influence. In comparing figures like average air temperatures and fog percentages of any one month with those of the corresponding month in previous years, or of other months of the same year, the fact should not be lost sight of that warmer and clearer conditions recorded may be due not so much to actually different conditions in the region as a whole as to whether or not the patrol vessels remained in the colder or warmer parts of the ice area during the greater part of the time under consideration.

The weather diagrams for each month of the active patrol season show graphically the wind directions and forces averaged for each 12 hours, the barometric curve, and the time and duration of fog and low visibility. In addition, the maximum, minimum, and average air temperatures, as well as percentages of the time that bad and poor visibility prevailed, have been given for each patrol month. As these figures were obtained in exactly the same manner as the corresponding ones for last year, the remarks made regarding them on page 50 of the 1928 Ice Patrol Bulletin apply with equal force to this season's values.

APRIL

Maximum air temperature, 57° F.
Minimum air temperature, 30° F.
Average air temperature, 40° F.
Visibility was less than 4 miles 35 per cent of the time.
Visibility was less than 2 miles 26 per cent of the time.

The first ship to go out on the 1929 ice patrol left Boston, Mass., for the eastward on April 1 during the early stages of one of the four deep barometric depressions of the month. Winds of gale force were experienced on the second day out, but, fortunately for progress and fuel consumption, they came from a following direction. The temperature and fog figures given above are those from noon of the 3d to the end of the month. The values for the first two and a half days of April were disregarded because the patrol vessel did not get out into the real ice-patrol area conditions of weather until after that time.

The monthly weather diagram plainly shows that fog was almost entirely absent until the morning of the 18th. From then on to the last of the month there was so much fog and bad visibility, however, that the figures for the whole month are slightly above what has here been called normal for the time and region. There were two prolonged periods of fog, the first with a low barometer on the 18th, 19th, and 20th, and the second with comparatively high barometer on the 27th, 28th, 29th, and 30th. The latter period of thick weather was terminated on the 30th by a shift of wind to the westward which followed upon the passage, far to the north through the Strait of Belle Isle, of the center of a large cyclonic storm.

Throughout nine half-day periods the wind force averaged Beaufort 7 or greater. This shows more boisterous conditions than obtained during April, 1928, for then only five such periods were recorded. During two of the cyclonic disturbances very heavy swells were noted with waves at least 30 feet high. This height was estimated by noting when the ship was on an even keel in the trough between swells the height above the water line at which the line of sight ran off tangent to the tops of the seas.

When over the cold water, even during the periods of good visibility, morning and evening star sights could very seldom be obtained because of a typical stratus cloud formation, resembling a high fog, that was very frequently noted at certain hours. It was dark and heavy early in the morning, but gradually thinned out during the course of the forenoon. Around 10 a. m. a pale sun could be seen through the thinner parts, and at this time the first observations of the day could be taken, usually without the use of any shade glasses in the sextants. From about 11 a. m. to 3 p. m. sun sights could usually be taken at will, but as the afternoon progressed the rolling, fairly low, cloud layer would form again, blot out the blue sky, and gradually thicken until the sun's disk could be seen no more. This sort of cloudiness did not hamper the search for ice greatly, for the visibility usually remained excellent just over the sea, the lower limits of the fog or cloud keeping at a uniform moderate level at all times. The delay in fixing position was the most serious thing involved, preventing as it did prompt and accurate determination of ship's position, berg drifts, currents, and exact limits of areas fully searched.

MAY

Maximum air temperature, 56° F.
Minimum air temperature, 34° F.
Average air temperature, 42.9° F.
Visibility was less than 4 miles 34 per cent of the time.
Visibility was less than 2 miles 27 per cent of the time.

May, 1928, had about twice as much fog and bad visibility, as usual, but in 1929 the figures for the month were back to normal again.

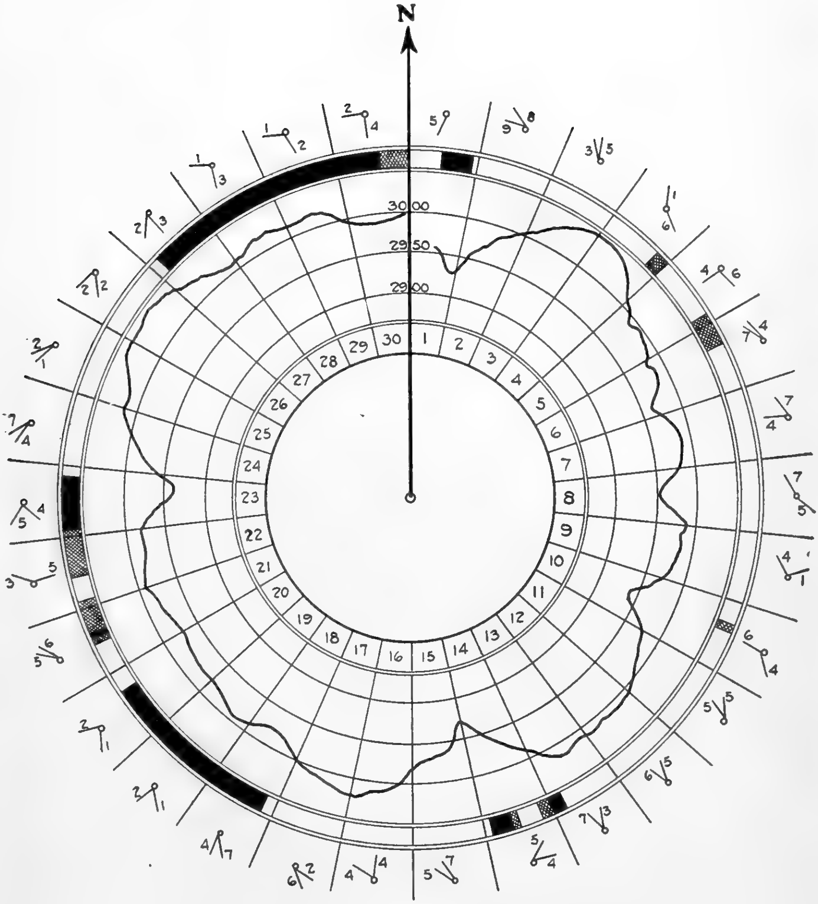

FIGURE 2.—Inner figures show day of the month; the next band out contains the record of the atmospheric pressure; the next outer one indicates the degree of visibility (black areas for visibility of less than two sea miles and cross-hatched areas for visibilities of between two and four miles); the outer margin shows the average direction and force of wind per 12-hour periods, midnight to noon and noon to midnight. Wind directions are toward the small circle in each case. Arrow indicates true north

The month was quite a pleasant one, taken as a whole. Air temperatures were quite low due to the unusual coldness of the ice-bearing waters, but there was much bright sunshine, and the air and sea temperatures slowly rose as the month advanced.

A few large cyclones passed northeastward across Newfoundland and Labrador, but the patrol vessels escaped all but the southern edges of these, and so had only two 12-hour periods of gales and no barometric pressure lower than 29.62, which figure was reached on the last day of the month. One feature noted on the weather maps made on board from synoptic data was a succession of large high-pressure areas that moved southeastward across the United States Atlantic Coast States and out to sea to join the Azorean High. Barometric pressures in the ice-patrol area became very high at times, exceeding 30.50 on five different days, which were invariably fine and sunny, though on two of these five days there was a slight haze that made bergs appear yellowish in the distance and disappear from sight when from 8 to 10 miles distant. Phenomenal visibility prevailed on the 2d, however, when the barometer was at 30.22 and light variable airs were blowing. At this time a berg about 50 feet high was seen from a height of eye of 30 feet when it was 38 sea miles distant.

The short period of fog experienced on the 11th with a high and rising barometer and north-northwest breezes was most unexpected. It occurred just before sunset over cold water near the junction of the Labrador Current and the Gulf Stream. The line of demarcation between the two waters was very ragged, for a little earlier in the day the patrol had cruised though alternate areas of cold and warm water each about 2 miles wide. The fog can best be explained by assuming that the surface air had just passed over a warm band of water and become moist and warm. A cold band of water happened to be to leeward of the warm band and, the critical conditions being just right, the moisture in the north-northwest breeze was condensed as fog as soon as the lowest layers of the warmed moistened air were chilled by contact with the small cold area in the sea. This unusual local fog occurred again on the 21st under almost identical conditions, except that in the second case the barometer was even higher, about 30.50 throughout the time. With northerly breezes fog is sometimes formed over the warm water, but its presence over cold water was very hard to explain.

Many other interesting meteorological phenomena were observed. For instance, the weather diagram shows that fog was finally caused on the 19th after southeasterly airs had been blowing for some time. As a general thing it takes a considerable time for southerly breezes to bring on a period of fog, and the further advanced the season is and the warmer the surface water is the harder it seems to be for the thick weather to get started.

When fog is formed over the cold water it is often very thin vertically with a clear blue sky showing overhead, as was the case on the 22d. Very often the rays of sunlight that reach the deck through the fog around midday have considerable warmth left in them, but not enough to remove the fog from the cold water as long as the wind continues to blow from warmer water toward colder. When conditions are rather finely balanced there is sometimes a tapering clear lane over the sea for a quarter of a mile or more directly to leeward of the drifting patrol ship, caused by the warmth escaping from the stack and hull.

The weather cleared slowly on the 23d after a shift of wind to the northwest. By evening the atmosphere was remarkably clear to the westward and sunset was followed by a very distinct green flash at the spot on the horizon where the sun had just disappeared. The next day, with its high barometer and gentle breezes, was about the brightest, clearest, and finest day of the whole season.

JUNE

Maximum air temperature, 70° F.
Minimum air temperature, 38° F.
Average air temperature, 51.2° F.
Visibility was less than 4 miles 42 per cent of the time.
Visibility was less than 2 miles 34 per cent of the time.

June, as is quite normal, had a higher percentage of hours with fog than either of the two preceding months. There was a marked change to general summer weather conditions. The procession of "Lows" along the American coast and up the St. Lawrence Valley slowed down, and a great high-pressure area in the ocean east of the United States and southern Canada stood opposed to a fairly constant condition of low pressure over North America. This distribution of pressures always gives the Grand Banks region a large proportion of gentle but steady southerly breezes, which are over the colder water areas, accompanied by foggy weather. An even greater number of times than during May there was low-lying fog with clear or partly cloudy sky plainly visible overhead. The bright sunshine on some of the days made fogbows and allied phenomena of common occurrence.

When cruising along the temperature wall many areas of fog patches were encountered. The search courses at such times frequently changed the surface water temperatures 11° F. in 11 minutes, say, from 48° F. to 59° F., and the air temperatures fluctuated almost as much and as rapidly. It would be raw and foggy over the cold water and damp and muggy over the warmer mixed water close by. During the first half of the month cold water pushed 150 miles to the southeastward to 40° N., 46° 40′ W., in a band about 20 miles wide. This stream was very difficult to search for ice because winds from

FIGURE 5.—For explanation of symbols, see Figure 2

any direction except northwest came from warmer water areas and usually gave fog.

The lowest barometric pressure for the month, 29.50, was reached on the 2d, but this depression was unaccompanied by gales, there being only a few hours of fresh breezes while the wind was hauling through south to southwest. The whole month saw no full 12-hour periods of gales, but there was a near approach to one on the 29th, when the wind averaged force 6 between noon and midnight.

During a period of good visibility on the 4th, which was a drizzly, overcast day, a berg was sighted about 10 miles off. While it was being approached the cloud blanket shut down closer and closer to the sea. When the berg was finally reached it was seen that its upper parts were completely hidden in a fog. It was then noted that the patrol ship's topmast and crow's nest were also in fog, though visibility still remained good at sea level. In a short time the fog shut down completely. The wind was light from the north-northeast and the air temperature was 42° F. This case is mentioned because it is quite the opposite condition to that much more often experienced where the upper layers of the air remain clear and only the lower layers are foggy.

On the 9th the ship was in warm mixed water near the long southeast push of cold water mentioned above. It had been foggy, and after the wind hauled to the north of west it remained so, instead of quickly clearing as usual. In order that the good visibility which, it was thought, must exist near by might not be lost for searching purposes, the patrol stood to windward and in a short time entered cold water, over which there was no fog whatever. Over the region of warmer water to the southeastward the pall of fog could be seen hanging throughout the remainder of the day.

There was noticeably bad refraction on four days. On one a 40-foot berg was sighted 26 miles away, and a few hours later the sun went down not like a round ball of fire but greatly flattened, like a vertical section through a watch being lowered face uppermost into the sea. On another day double horizon lines were noted for some hours until continuing southerly breezes finally brought on fog and rain.

During several foggy days which were spent along the temperature wall, copious showers were experienced. Some of these were regular tropical downpours. From ship reports received, it is believed that at the same time bright weather was prevailing over the Gulf Stream drift, and the usual Grand Banks fog with clear sky overhead was prevailing farther north well inside the area of cold water. At other times, when cruising near the temperature wall, squalls from varying directions were experienced, all of which indicates that at times along the line of junction of Labrador Current and Gulf Stream there is

an unstable area, where uprushes of air, indrafts, and such activities take place.

JULY

Maximum air temperature, 73° F.
Minimum air temperature, 43° F.
Average air temperature, 59.8° F.
Visibility was less than 4 miles 38 per cent of the time.
Visibility was less than 2 miles 32 per cent of the time.

Previous to the 1929 season the ice patrol has always been discontinued by the middle of July, but the 1929 ice conditions necessitated its continuance until August 3. The July meteorological information given here and on the July weather diagram is, therefore, for the first time that for the full month. The patrol was discontinued so early in August that no separate discussion or weather diagram has been prepared for the time after July 31.

July was marked by very weak barometric gradients with accompanying fine moderate weather. The weather maps showed a tendency for a low-pressure area to remain over the central portions of North America and for high pressures to prevail over great areas of the North Atlantic Ocean and over the United States Middle Atlantic States. There was a marked increase in sea and air temperatures in the ice-patrol area because of continued solar warming, and a falling off in fog percentages as compared with the previous month. The last three days of the month were days of dense fog because of persistent southerly breezes and airs, and this fogginess was continued, over the colder waters along the eastern edge of the Grand Banks at least, without a break until after the patrol was discontinued on August 3. This shows that an advanced summer season, while it lessens the hours of fog over the warm and the warmed mixed waters, has but little beneficial effect over the southern reaches of the Labrador Current proper. It was often possible to pick clear-weather areas and to remain in them by working toward cold-water areas during northerly breezes and running toward warmer water when southerly breezes began to cause fog.

GENERAL REMARKS

Because much interest is shown by shipping in the patrol vessel's weather, the conditions prevailing were always incorporated in the routine ice broadcasts. Placing the data in these messages not only assured as wide a dissemination of it as possible but saved time and effort for all concerned through the cutting off of many inquiries regarding weather conditions that experience has shown would otherwise have come in from single vessels.

Twice daily a coded weather report was dispatched to the United States Weather Bureau, Washington, D. C., and at the end of each

cruise the regular Weather Bureau forms were filled in for the patrol period and mailed upon arrival in port. The coded dispatches to Washington always included, when available, the weather at one or more ship stations well separated from the patrol. These composite messages were transmitted direct to Washington at scheduled times which were sufficiently early to insure that the data would be available for use in making up the Weather Bureau's ocean forecasts. The same weather information sent to Washington was transmitted via Canadian coastal radio stations to the Canadian meterological officials at Ottawa, Ontario, for their use. This was a new departure, beginning with the 1929 patrol season.

An average of 60 water-temperature reports were received each day from vessels within the ice-patrol area, which may be defined as the area bounded by latitudes 39° and 48° N. and longitudes 43° and 56° W. Shipping was frequently reminded of the need of the patrol for reports by broadcasts worded about as follows: "All vessels while within the ice-patrol area are requested to transmit to the ice-patrol vessel, call NIDK, the following every four hours: Ship's name, G. M. C. T., latitude, longitude, course, speed, temperature of water, weather conditions, and any ice or other obstructions sighted." In response many of the ships included in their water-temperature reports all the necessary meterological elements, for the most part, no doubt, very carefully and regularly observed. When a number of the best-cooperating ships were well scattered along the tracks there was a wealth of material to choose from, and most of the remaining time there were at least a few vessel reports to consider when making up the Weather Bureau dispatches. Only the latest, most reliable, and best situated reports were marked for coding and transmission to shore.

On the patrol vessels, especially during foggy periods, the weather obtaining at the positions of reporting vessels would be frequently plotted on suitable ocean charts. The limits of fog sheets, rain areas, good weather, gales, and other conditions could then be seen with considerable accuracy and ease. Detailed weather information obtained from reports so plotted was several times furnished the United States Weather Bureau officials on request during the anxious times just prior to projected trans-Atlantic airplane flights.

Following the customs of previous years, two weather maps were made up each day from data contained in the general synoptic broadcasts transmitted by NAA, at Arlington, Va. Supplemented by the weather reports received from shipping, these maps were used for forecasting the local weather. They proved most useful for use in connection with planning the patrol's cruising as well as interesting. With their aid it was always possible to know what weather conditions were prevailing in a large area to the westward. These conditions, it

is very soon clear to observers on the patrol ships, control to a great extent the immediate future course of weather in the ice-patrol area.

DEPTH SURVEY CARRIED OUT BY THE SONIC METHOD

Throughout the 1929 ice-patrol season both the *Tampa* and *Modoc* were equipped with commercial instruments for determining the depth of the water by sonic means. It was usually possible to use these instruments successfully so long as the ships remained inside the 1,400-fathom curve. On smooth days when the sets were working especially well they could be used in water up to about 2,000 fathoms deep. Whenever echoes could be obtained from the sea bottom frequent soundings were taken and recorded.

One hundred and ninety-one values that were obtained when the vessels' positions were well fixed by sights have been corrected for certain errors due to actual conditions of salinity, temperature, and pressure in the water column and forwarded to the United States Hydrographic Office and to the United States Coast and Geodetic Survey for use on charts of the North Atlantic Ocean. Altogether many times 191 values were recorded, but the great majority of soundings, though useful for immediate navigational purposes, were taken when the exact geographical position was in some doubt due to such things as abnormal refraction, cloudiness, darkness, and fog. The depths obtained when the position was uncertain were without exception discarded so far as giving them consideration for hydrographic use was concerned. The area where the patrol vessels cruised in 1929 has been rather well sounded out, and for this reason nothing but the best work of the season was considered worth keeping.

Two navigators worked out the different positions of the ships independently for check purposes, so the locations listed with the sounding values saved are based on double work and are believed to be as nearly correct as such values can be on board a ship on ice-patrol duty in the Grand Banks region. Of course some of the positions are closer to being right than others. The radius of error probably varies from next to nothing at all up to a maximum of about 10,000 yards.

ICE OBSERVATION

The varying ice conditions that existed during the first nine months of 1929 in the North Atlantic south of the forty-eighth parallel are discussed here. The monthly ice charts (figs. 6–11 inclusive) show plainly where the ice at different times was located with respect to the coast lines, principal steamship tracks, and other features of the Grand Banks region. They furnish a far better means than written remarks for comparing the change of ice conditions from month to month and those of certain months of one year with corresponding months of another. United States Hydrographic Office Miscellaneous Chart 2,511 was used as the base map for plotting all ice data.

Iceberg totals and ice conditions are based during the actual active patrol season on first-hand information, supplemented by that received by radio from ship and coast stations. Reports of ice published weekly in the United States Hydrographic Bulletin and those received from Canadian Government authorities are depended upon during the inactive season when there is no patrol ship in the vicinity of the Grand Banks.

The large number of ships on the various tracks that cooperate by reporting regularly makes much care necessary to keep duplications from unduly swelling the berg totals. Suppose, for instance, that 10 ships all pass along the same general line and each one reports four bergs to the patrol from about the same locations on the same day. Only one of these reports of ice can be considered for broadcast and statistical purposes, for it is obvious that all the ships have seen and reported the same ice.

Probable drift tracks of ice are rather well known from experience, and the general principles of these drifts are explained in conjunction with the charts on pages 68 and 69 of the Ice Patrol's Bulletin for 1927. In addition, particular detailed drifts and variations from the general rules can often be forecast after a study of the cruise isotherm and ice charts that are always kept up to date on the patrol vessels. Bergs reported from one position on one day, therefore, are frequently assumed to be identical with bergs reported from two or three and sometimes even five or six days earlier from different locations, and are eliminated from the statistical totals. But no reported berg is omitted from the broadcasts unless it is pretty definitely known to be identical with some other reported berg. It is certainly wiser to broadcast the presence of slightly more ice than exists rather than to eliminate from the reports mention of any ice that may still remain.

In accordance with the practice of all previous years, it was considered that the start of a new month cleared off the statistical slate, all bergs reported anew on or after the first of a month being considered once more for determination of monthly totals, whether or not they had already been reported.

Nine months instead of twelve are discussed here because complete ice information for the last three months of the year is not at hand as this section is being written. The 1930 Ice Observation and Ice Patrol Service pamphlet will contain the discussion for October, November, and December, 1929. As these three months share with January the distinction of being the very lightest ice months of the year, their omission from this publication is really of no moment.

Frequent reference is made throughout this and other sections to the "ice-patrol area." This never refers exclusively to the rather limited area south and east of the Tail of the Banks that can be physically covered by the efforts of the ice-patrol vessels themselves. It always includes all that area between the thirty-ninth and forty-eighth parallels and the forty-third and fifty-sixth meridians, which is constantly being crossed and recrossed by reporting vessels. In general, during clear weather all parts within these limits that are at all near the several steamship tracks are well covered either by the patrol or for it. During good weather conditions the situation may be said to be well in hand, and, therefore, advice can be given about ice conditions with confidence to vessels that may be crossing the ocean hundreds of miles to the north or the south of the actual limits of vision of the ice patrol. During the long periods of fog, however, when the eyes of reporting vessels as well as those of the patrol are blindfolded, the exact status of affairs with respect to the location of the ice is not so well known, and then extra precautions are regularly advised both in the broadcasts and in the special ice-information messages. The patrol's experience is that bergs can be detected only when they can be seen. It is only rarely that bergs are sighted or reported during thick weather or darkness, though undoubtedly the the brightest lookout is kept for them during just those times.

The ice-patrol area as defined above does not by any means set a bound to the patrol's interest, information, or service. Reports of ice and obstructions that come in from far to the eastward of the forty-third meridian and from far to the northward of the forty-eighth and even forty-ninth parallels are gladly received and when on hand are invariably included in the broadcasts. Far to the westward, also, the changing field-ice conditions in the approach to the Gulf of St. Lawrence are followed and reported as closely as the radio advices received make possible.

Water-temperature reports from the area surrounding the so-called ice-patrol area are also frequently received. They are always care-

PLATE X.—Medical officer of the *Tampa* on board a French fishing vessel off the eastern edge of the Grand Banks. There are between 20 and 30 men on each of these sailing vessels, and usually at least 1 member of the crew is in need of medical treatment. Complaints range from injuries and sores to abscessed teeth and tuberculosis

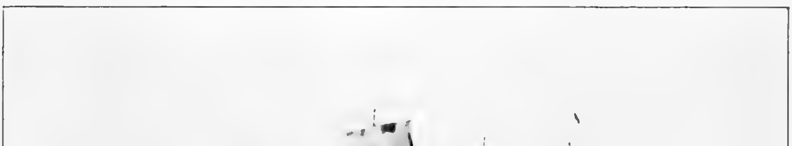

PLATE XI.—Dory pulling from a French fishing vessel to the *Tampa* with letters to be posted. The fishermen are frequently at sea for seven months at a stretch, and are always eager to send letters home and to exchange fish for articles of food which will add variety to their diet

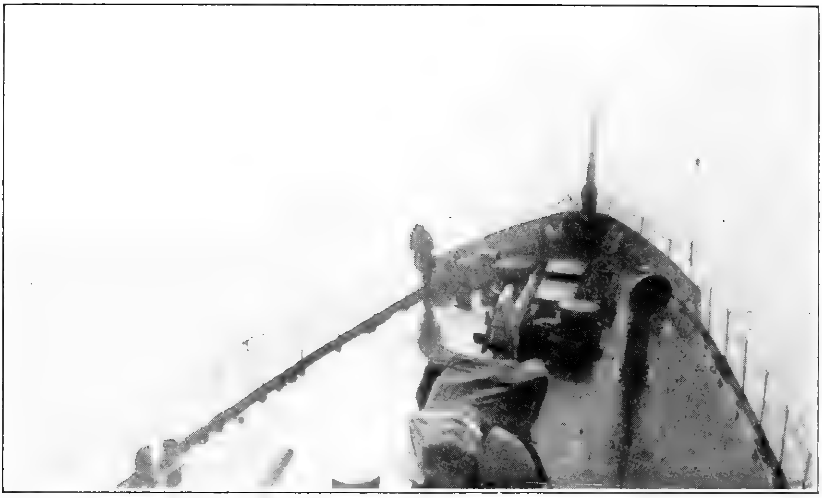

PLATE XII.—For approximately one-third of the time the ice patrol cutters are blindfolded by dense fog like this. The fog is usually brought on by long continuing light southerly breezes. Often it is so thin vertically that the sun is able to shine down dimly to the water, as here

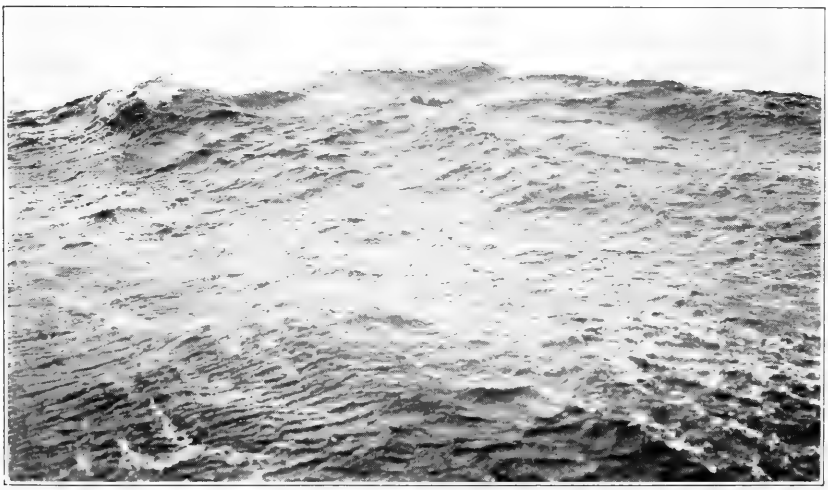

PLATE XIII.—There are a number of storms each season. These, as well as the fog, interfere with the scouting and scientific programs. This wave was photographed from the stern of an ice patrol cutter while not far from the tail of the Grand Banks

fully plotted and studied to see what bearing they may have upon ice, current, and weather conditions now obtaining or that may soon obtain within the area that is most intimately under the cognizance of the patrol.

JANUARY

There were no reports of ice from the region of the Grand Banks. Some field ice, however, was carried seaward from the Gulf of St. Lawrence by the Cape Breton Current and was reported during the latter part of the month from 60 miles southeast of Cape Breton.

FEBRUARY

Considerable field ice from the Gulf of St. Lawrence was reported from areas about midway between Sable Island and Cape Breton. Further east the first field ice of the season began to drift south into the international ice-patrol area proper, where it was reported frequently from the region just north of the Grand Banks. By the end of the month the southernmost limits of this latter ice had pushed south of the forty-seventh parallel along the line between Cape Race and the northeastern shoulder of the Grand Banks, and on the 28th there was a report of field ice and growlers extending south in the main branch of the Labrador Current along the eastern edge of the Grand Banks to 46° 25′ N., 47° 40′ W. So far as is known during this month no bergs drifted south of the forty-eighth parallel in company with the field ice from the north. The ice map for February, 1929, is almost identical with that for February, 1928.

MARCH

The ice map for this month also bears a remarkable resemblance to that for the corresponding period of the preceding year. The ice of March, 1929, being apparently somewhat heavier and of greater extent, however, gave the first hint that an unusually heavy ice season was about to develop. Vessels passing north of Sable Island reported large patches of loose field ice from the Gulf of St. Lawrence to be extending to about 120 miles southeast of Cape Breton. Some of these patches over the northeastern limits of Banquerau Bank were described as heavy.

Ten degrees to the eastward, along the eastern edge of the Grand Banks, the first bergs of the season began to be reported wherever the trans-Atlantic traffic sighted the southward moving field ice. Indeed, throughout most of the area northwest of the line from Cape Race to Flemish Cap and on both sides of the line from Flemish Cap to 44° 30′ N., 49° 00′ W., field ice and bergs were frequently reported together.

APRIL

No reports were received of the Gulf of St. Lawrence field ice but in the Labrador Current along the eastern edge of the Grand Banks there appeared a far greater amount of all kinds of ice than usual for the season. In the first place a great amount of field ice seriously obstructed navigation within the area partially bounded by lines running from Cape Race to 44° 20′ N., 48° 30′ W., thence to 47° 30′ N., 46° 30′ W., and thence northwestward past the forty-ninth parallel, and so out of the field of observation. Everywhere this field ice was more or less thickly studded with bergs.

Toward the end of the month ship reports indicated that the limits of the field ice had retreated rapidly to north of the forty-seventh parallel. After the flat ice was melted by sun, wave, and warmer water the large bergs, being much more resistant, remained to continue their southward drift toward the Gulf Stream waters. The great majority of the April bergs were situated between the 50-fathom curve of the eastern edge of the Grand Banks and a line located 60 miles to the eastward of it. The most southerly bergs of the month were located along the direct southerly extension of this ice stream, where they almost reached to the forty-second degree of north latitude in longitude 49° 30′ W.

There was also a very distinct curving of ice and cold water to the westward around the Tail of the Banks. If this outlet had not existed it is very probable that the southward push of icy waters would have been greater and would have sufficed to carry bergs across the westbound B tracks to the south and southeast of the Tail.

About the middle of the month reports showed that scattered bergs were rapidly advancing southeastward into and across the area of warm surface water to the east and west of 42° 50′ N., 44° 30′ W. One of these bergs actually crossed the westbound B track from Fastnet, in longitude 43° 50′ W. This push of bergs was quite alarming, and was one of the factors that made the patrol recommend a shift of tracks south to the extra southern or "A" lanes on April 19, though, as matters turned out, after that date there were very few further reports of threatening bergs in the eastern part of the ice-patrol area. The warm waters rapidly melted the southeasternmost of the invading bergs and their ranks were not filled by new levies from the continuous procession moving south along the eastern edge. During April, 1928, there was a southeasterly push of bergs very similar to the one of 1929. The feature this year, however, in common with all ice conditions about the Grand Banks from April on, was far heavier and more serious. This year the patrol ships were prevented by the ice just below the Tail from investigating the southeastern sector themselves; therefore a careful study of the subsurface conditions in the latter area could not be carried out. The bergs, as shown

by numerous reports, were apparently drifting southeast across warm water at right angles to the surface isotherms and to the usually conceived direction of the Gulf Stream drift. The 120-mile berg-free separation of the southeasternmost bergs from the ice just below the Tail precludes, when combined with a study of the successive reported positions of the ice, the belief that the former group was made up of bergs that had earlier drifted south past the Tail and got into a northeast-flowing current.

MAY

Early in the month the two latest reports for the year were received of the Gulf of St. Lawrence field ice, both from the northern end of St. Pierre Bank. In the Grand Banks region farther to the eastward great changes took place in the ice situation. Throughout the month the surface waters north of the forty-second parallel remained on the average considerably colder than in 1928. Nevertheless, the effects of the advancing sun caused field ice that drifted south of Newfoundland to melt with considerable rapidity and the southern limits of the pack ice to retreat apace. Before the end of the month field ice was reported for the last time in 1929 from anywhere in the ice-patrol area.

Bergs were present in almost unheard-of numbers northeast of the Grand Banks, especially in the area extending 150 miles northeast from the line between 48° 15′ N., 51° 10′ W., and 45° 50′ N., 47° 10′ W. The patrol vessels, as usual, watched the southernmost ice and in the cases of a few critical bergs were able to determine their drift tracks. These are located in the general vicinity of the Tail and are shown by dotted lines on the ice chart.

During May there was an unexpected falling off in bergs south of the forty-third parallel and a lull in the menace to the United States, Europe tracks. Almost all bergs that reached the latitude of the Tail curved closely around it and passed to the westward. Instead of continuing northwestward along the southwest edge of the Banks, some of this ice, as it had done during April, turned offshore and pushed southward along the fifty-first meridian from the forty-third parallel. However, the southernmost ice of the month, which was along this line, failed to reach even the westbound "B" track to Boston by over 30 miles.

The ice chart for May shows an apparent lack of bergs along the eastern edge of the Banks between 44° 00′ N. and 45° 30′ N. This is probably due to the fact that the area concerned was crossed so little by reporting steamers that many bergs undoubtedly escaped observation there. The shifting north of the Canadian tracks as soon as the ice conditions permit in the spring leaves a wide comparatively unsearched gap between the usual seat of operations of the ice patrol

in the latitude of the Tail and the next set of traffic lanes to the north.

JUNE

The severity of June, 1929, from an ice standpoint, can best be seen when one compares the month's ice map with that for June, 1928. (See United States Coast Guard Bulletin No. 17, fig. 10.) Though the chart for the latter month shows a total number of bergs south of the forty-eighth parallel somewhat in excess of normal, and one berg with an extreme southerly drift, the total number of bergs in the ice-patrol area during June, 1929, was several times as great and the situation was considerably more dangerous.

The surface waters north of the Banks, along the eastern edge, and to the westward of the Tail continued to be abnormally cold. A feature of the month was the recurrence of a great number of bergs south of the Tail. These bergs extended from 43° 10′ N., 53° 00′ W., to 42° 40′ N., 48° 00′ W., and along a 190-nautical-mile front the foremost of them pushed farther south than did any bergs during May.

North of this group, except along the tracks of the few cooperating vessels that crossed the eastern edge, there is a relative scarcity of bergs plotted, but, as stated above in the discussion for May, the lack of bergs plotted in certain areas can often be credited to lack of reporting vessels rather than to actual lack of bergs. In June the Canada-Europe traffic was on the Cape Race tracks, still farther north than it had been during the preceding month. Had the waters along the eastern edge been well covered by the patrol ships or by reporting vessels, doubtless a considerable number of bergs that remained unreported would have been found.

From along the Cape Race, or F tracks, great numbers of bergs were reported. Even there, however, they noticeably thinned out in numbers as the month progressed. During June shore stations located along the Newfoundland coast between Cape Race and St. Johns began to sight bergs for the first time in 1929. This was the result of the bergs in the northern part of the ice-patrol area being located on the average much farther westward in the ocean than earlier in the year. The disappearance of the field ice with the advance of the season is regularly followed by a westward movement of the average of the drift tracks of bergs north of the forty-seventh parallel. A continuation of such a tendency finally results in a failure of supply of bergs to the narrow cold stream that runs south along the eastern edge. It is just as though the supply of grain to the hopper of a mill were cut off by the slow deflection of the grain chute that keeps it filled. Even though the bergs should keep coming down in undiminished numbers across the forty-eighth parallel (which they never do), the farther west they come down in the ocean the less is

their chance of getting south past the islands and rocks of the Labrador and Newfoundland shores and past the shoals and slack waters that exist along the northern edges of the Grand Banks.

JULY

Though still abnormally heavy from an ice standpoint, July, 1929, when compared with the preceding month, shows a great decrease of bergs along the Cape Race tracks. The ice extended a little farther to the westward around Cape Race than in June, but it did not drift through the gulley off this point beyond longitude 53° 10′ W. Many ships went east and west past Cape Race, and if any bergs had been located farther to the westward they would certainly have been reported.

The few bergs reported from unusual positions near 45° 00′ N., 54° 30′ W., and 43° 00′ N., 53° 00′ W., were doubtless straggling remnants of the ice that had made its way so freely to the westward around the Tail during the previous month. The westward tendency in the southern part of the ice-patrol area was definitely stopped early in July by the pushing northeast to the Tail of an undulation in the northern limits of the Gulf Stream. This invasion of warm surface water almost entirely obliterated the extension of cold current that had previously passed westward around the Tail. At the same time it caused the southern branch of the Labrador Current to increase in power and extension until it was carrying bergs southeast almost to 41° N. 48° W. The United States-Europe ships had been recalled from the extra southern A tracks, and such an unlooked-for final push of ice and cold water caused the patrol deep concern. From the 11th to the 24th it sent a number of large bergs drifting eastward right along the path of the liners on the westbound B tracks.

During the last few days of the month the southernmost bergs melted under the eyes of the patrol. Their final disintegration was quite rapid because of midsummer air and water temperatures and apparent mixture of the surrounding northern waters with the Gulf Stream drift. As the southern limit of the ice gradually retreated northward the patrol followed it along from berg to berg, for the push of the cold waters had weakened and no new ice was coming down to take the place of that melting below the Tail. The exact status of affairs a little to the northward along the eastern edge could not be determined during the closing days of the month because persistent fog remained over the narrow stream of pure Labrador Current water that according to surface temperatures, still extended to just south of the forty-third parallel.

AUGUST

The long, heavy ice season finally ended during this month. August saw but one report of ice from the ice-patrol area proper, that of a berg on the 3d near the Newfoundland coast just north of St. John's.

There were reports of five bergs early in the month from north of the Banks, but none of these were ever reported from south of the forty-eighth parallel. Constant fog prevailed over the narrow cold stream of cold water along the eastern edge of the Banks until after the ice-patrol service for 1929 was discontinued on the 3d, so it is just possible that an unreported berg or two may have disintegrated there unseen.

SEPTEMBER

A berg was reported on the 19th from 44° 05′ N., 44° 30′ W.

GENERAL REMARKS AND SUMMARY

The above monthly discussions and the charts following this section show in general how ice was distributed southeast of Newfoundland throughout the 1929 ice season. A narrative account of the ice seen from the patrol vessels, together with remarks on circumstances attending its disintegretion in some instances, can be found, respectively, in the sections devoted to the cruise reports and oceanography.

The following tabular summary shows how the 1929 monthly berg totals compare with those of the average year, the latter being based on a study of iceberg reports from south of the forty-eighth parallel for the period 1900–1926:

Month	Bergs south of 48° N. in 1929	Bergs south of 43° N. in 1929	Bergs south of 48° N. normally	Bergs south of 43° N. normally
January	0	0	3	0
February	0	0	10	1
March	45	0	36	4
April	332	32	83	9
May	460	9	130	18
June	376	72	68	13
July	107	21	25	3
August	1	0	13	2
September	1	0	9	1
Total	1, 322	134	377	51

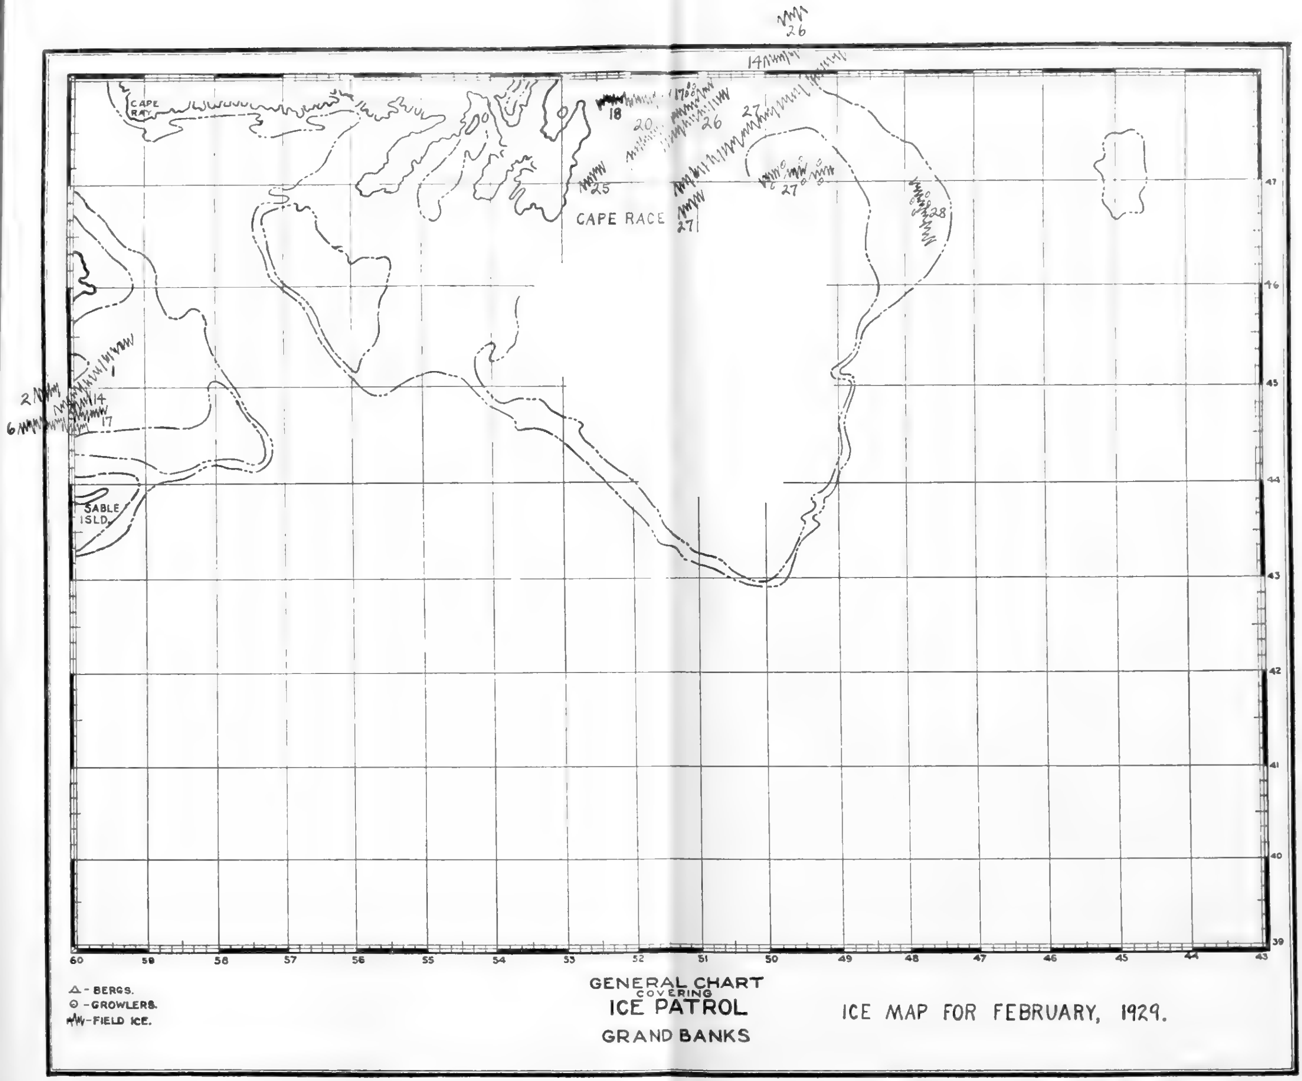

FIGURE 6.—February ice map. No known icebergs were south of the 48th parallel during the month

100277—30. (Face p. 82.) No. 1

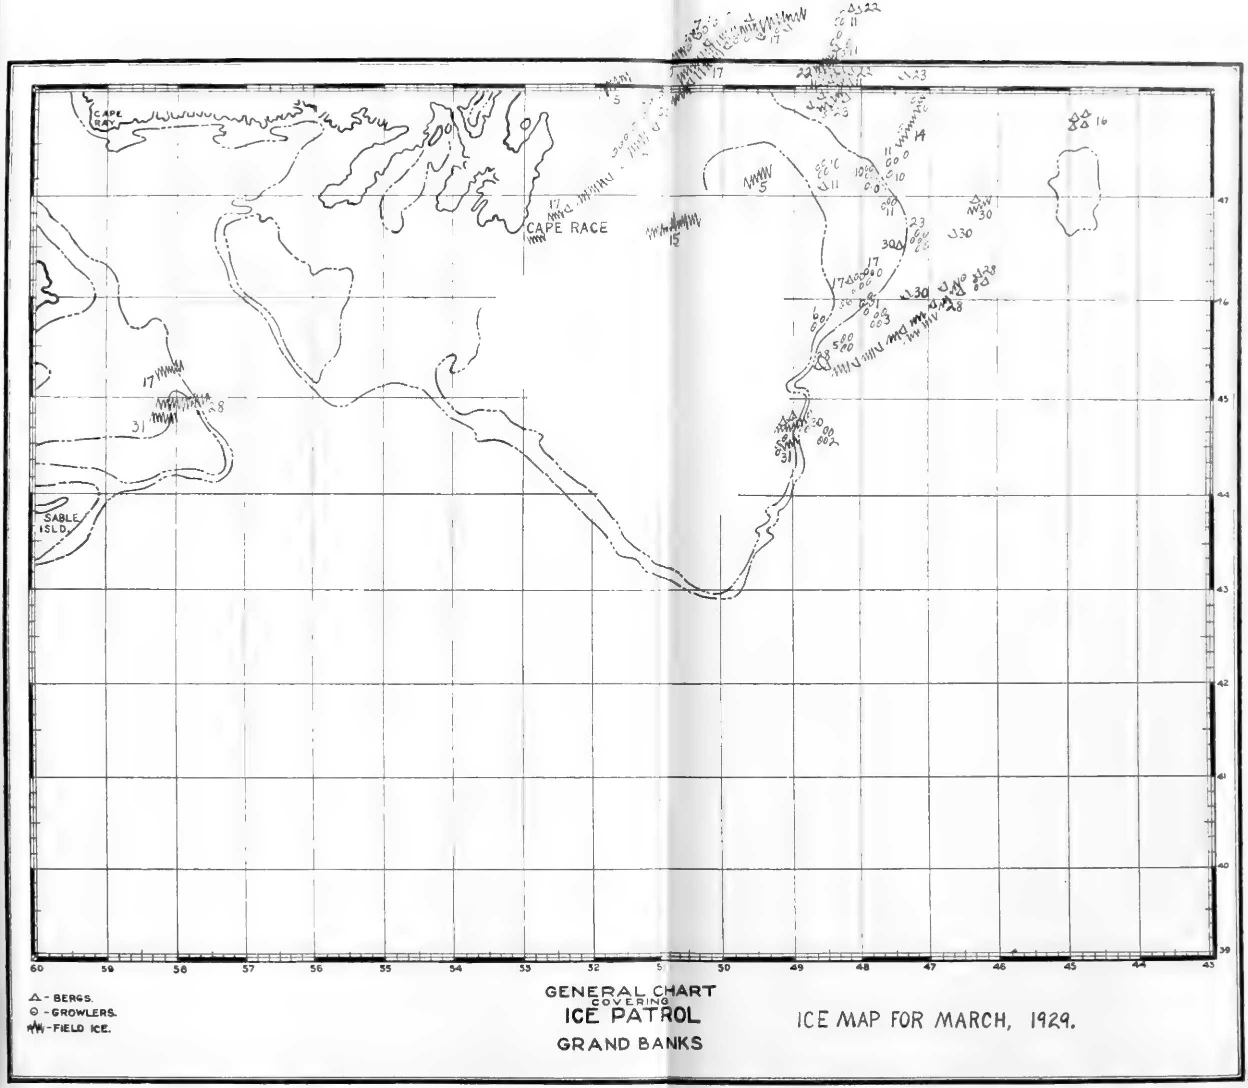

FIGURE 7.—March ice map. Forty-five known icebergs were south of the 48th parallel during the month 100277—30. (Face p. 82.) No. 2

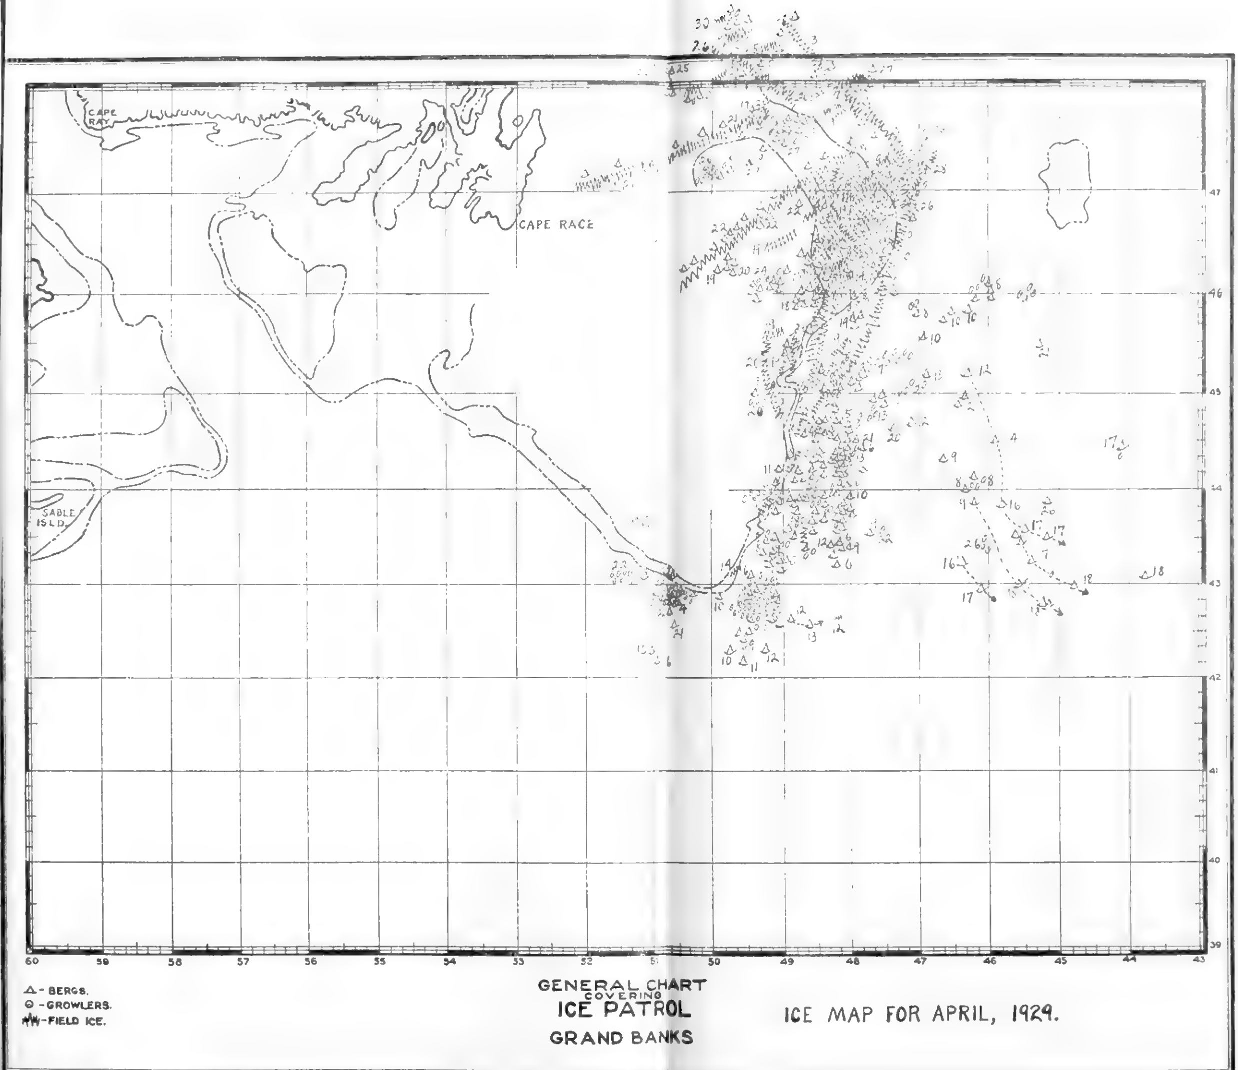

FIGURE 8.—April ice map. Three hundred and thirty-two known icebergs were south of the 48th parallel during the month

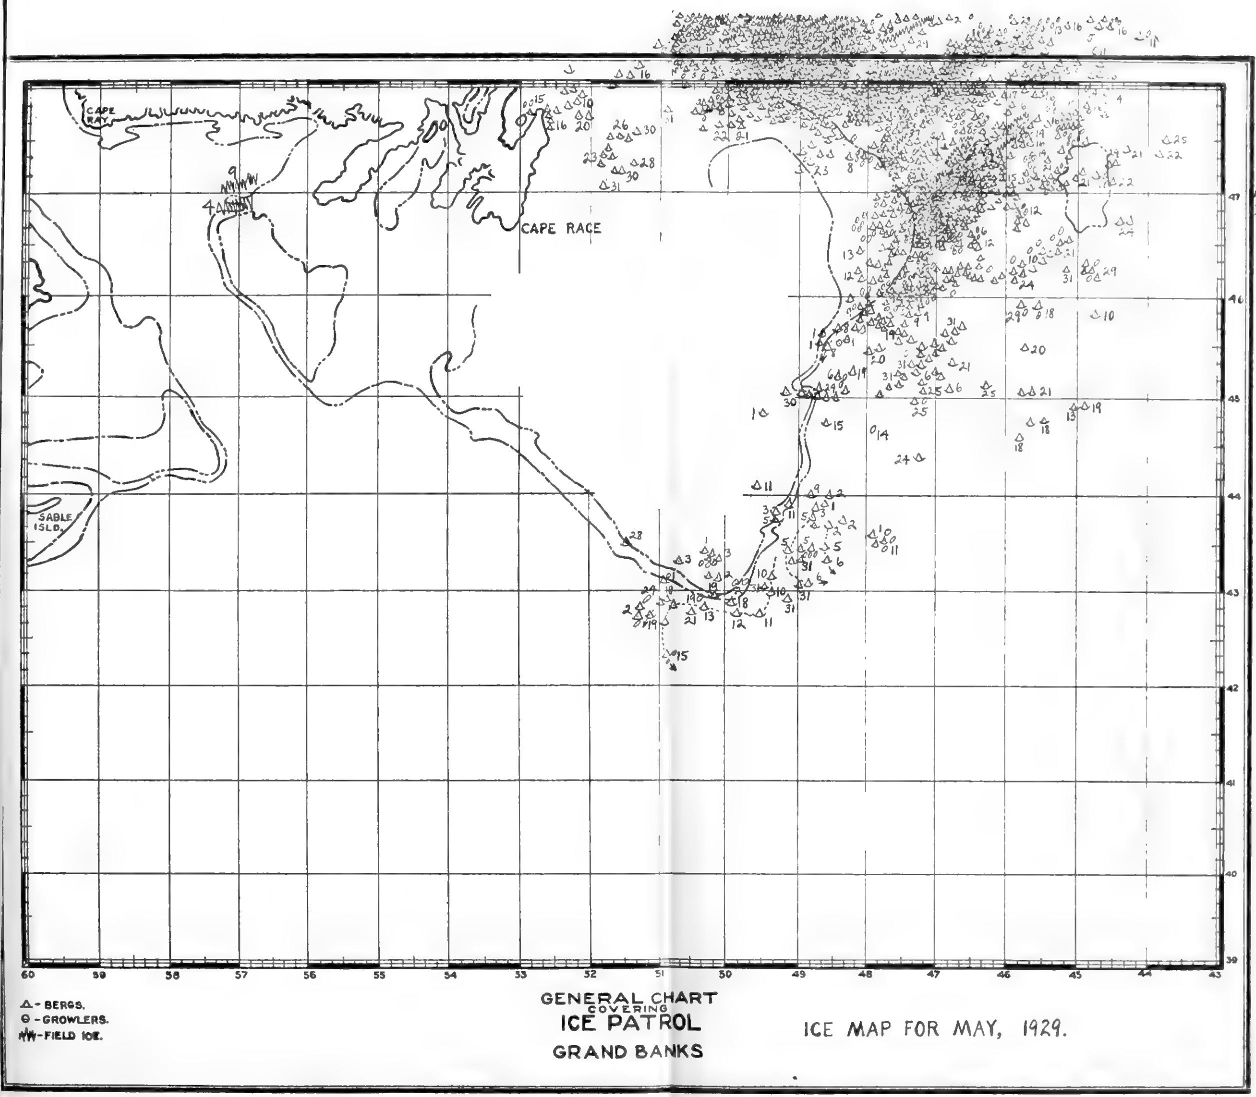

FIGURE 9.—May ice map. Four hundred and sixty known icebergs were south of the 48th parallel during the month

100277—30. (Face p. 82.) No. 4

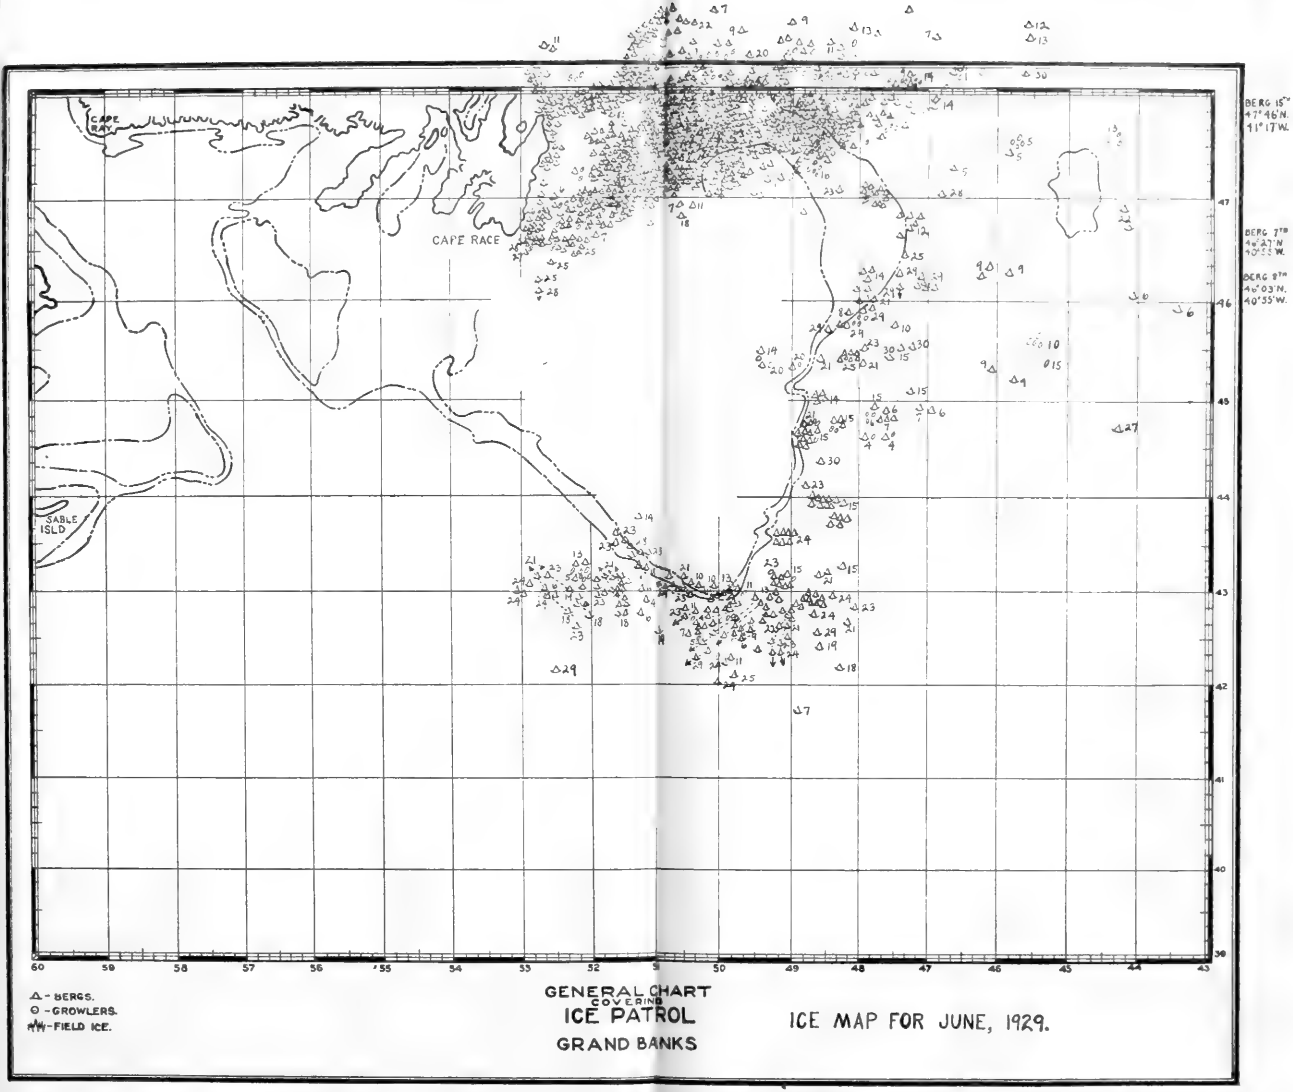

FIGURE 10.—June ice map. Three hundred and seventy-six known icebergs were south of the 48th parallel during the month

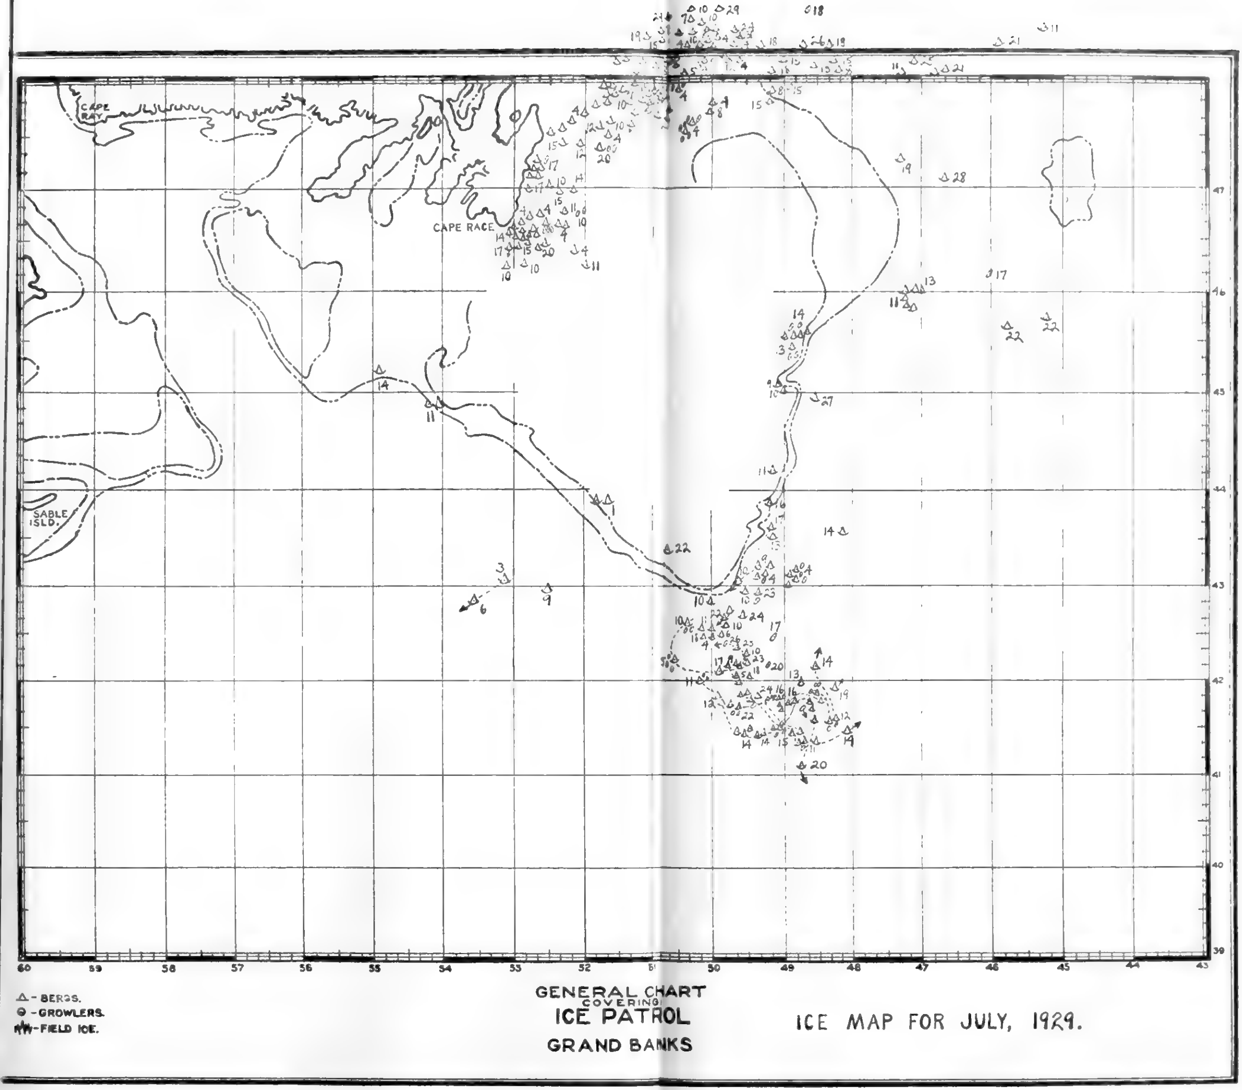

FIGURE 11.—July ice map. About 100 known icebergs were south of the 48th parallel during the month

100277—30. (Face p. 82.) No. 6

SOME OF THE ICE PATROL'S PROBLEMS, AND HOW IT ATTACKS THEM

The primary duty of the ice patrol is locating and broadcasting the position of all ice near the steamship tracks which cross the North Atlantic south of Newfoundland. The patrol service is maintained to assure, if possible, that vessels using these tracks will not run unwarned into ice-infested waters.

The patrol's responsibility is certainly not the safe passage of persons, vessels, and freight across the ice-patrol regions. That is, indeed, the final aim of the ice patrol's work, but the safety of each individual ship is something not under the control of the ice-patrol officials. Safety from dangers incident to collision with ice is dependent upon the judgment of the individual shipmasters in estimating the situation ahead of them. The patrol's broadcasts give these men a certain amount of late information, which is undoubtedly useful as a guide for shaping their course and speed policies past the Grand Banks.

One patrol vessel is out on duty at all times during the heavy ice season. The fuel capacity and other limitations of the vessels that have been used to date are such that they can cruise at about 10 knots during daylight hours of good visibility during their 15-day duty periods in the ice regions, and ordinarily no more. Greater work than that they can not do because of the need for fuel to carry the ships to and from the ice area, to evaporate sea water for domestic and boiler purposes, to supply demands for steam during long stand-by periods of fog, darkness, and storm, to retain position in currents, and for emergency reserves.

Bad visibility and bad weather together are so prevalent that on the average the patrol can count on no more than 150 hours of efficient searching weather per 15-day period of patrol duty. During these 150 hours the patrol ship averaging 10 knots can run 1,500 sea miles and can sight bergs at an average distance of not over 15 miles on either hand. In other words, the patrol vessel herself can examine not over 45,000 square sea miles of water area per average patrol cruise, even when every available hour of good visibility is utilized to the full for search purposes.

Some ground is lost because of doubly searched areas that unavoidably exist about the corners of the search patterns. Other reasons, such as necessary overlapping of searches made on different days due

to indeterminate differential surface drifts of neighboring sea areas, and large ship drifts during periods of darkness and low visibility, cause additional losses. As a matter of fact, a good figure to take for the maximum actual area that can be well covered for ice by one patrol ship per 15-day patrol cruise is 30,000 square sea miles.

The area about the Grand Banks that most frequently contains bergs and to which it is desirable to confine most of the patrol's activity lies between longitudes 43° and 54° W. and latitudes 40° 30′ and 48° N. Deducting the area of the Avalon Peninsula of Newfoundland and that of a warm iceless portion in the southeastern corner of this region, it will be found that the total area south of the forty-eighth parallel which is most likely to contain ice contains about 168,000 square geographical miles. Some of the areas over the Grand Banks themselves are not frequented by trans-atlantic traffic. There is, besides, very little sustained current in the shoal water. Therefore, the total area which must be most closely watched can be reduced to about 150,000 square geographical miles.

North of this great southern ice area and extending eastward for several degrees of longitude from the North American coasts, the waters are particularly liable to be congested with ice. It is normal for unnavigable field ice to exist over broad areas immediately north of the forty-eighth parallel during several winter and spring months. The same waters are liable to be more or less thickly strewn with bergs throughout the whole year. Though ice conditions vary in different localities for various reasons, it is true, generally speaking, that the farther north of the forty-eighth parallel one goes along the North American coast the worse will be the ice conditions met. This holds true all the way up into the Arctic regions that are choked all year round with impenetrable field ice.

The serious ice conditions likely to be met at any time to the north of the Grand Banks and the forty-eighth parallel are doubtless well realized by the masters of all vessels crossing in the higher latitudes, so for all practical purposes this area can be considered as beyond the ice patrol's particular sphere of action, though not at all beyond its sphere of experience, interest, or knowledge. Ice information received in the form of reports from the northern sections is always placed in the broadcasts and retained for about five days before being dropped. Any vessel requesting special information from the patrol ship regarding ice in the area north of the forty-eighth parallel will usually be able to get valuable information.

There have been occasional reports of bergs to the west, south, and east of the usual ice area between 43° W. to 54° W. and 40° 30′ N. to 48° N. Ice in such locations, however, may be considered as due to extraordinary berg or current conditions. The ice-patrol ships themselves can not attempt to locate ice in waters where it is

only phenomenally present any more than they can keep track of all the ice in the tremendous ice regions of the north. As a matter of fact, if the patrol limits its cruising activities to the important ice area of 150,000 square sea miles about the Grand Banks, it is confronted with a very sizable problem, for it has been shown that in a full 15-day cruise period the patrol's own searching can be made to cover but about one-fifth of such an area.

The result is that the patrol is compelled to concentrate on the most critical parts of the 150,000 square sea mile ice area south of the forty-eighth parallel. It relies upon reports from passing ships for its knowledge of ice in many parts of this area, as well as in the surrounding northern and southern regions, that on the one hand always, and on the other only exceptionally, contain ice.

It may be of interest to state here what takes place on the patrol vessel when ice or water temperature reports are received. Copies of all these incoming messages are promptly taken to the chart room and delivered to the ice-observation force. They first scrutinize the reports for errors. The tracks and approximate positions of all regularly reporting steamers while in the ice-patrol area are kept plotted on special charts. If a new report is from an obviously improbable location, some distance from where the reporting ship should have been at the time of origin of the message, the value is thrown out if an ordinary temperature report. If it is an ice report, or a water temperature value from an area that few vessels have been through recently, an inquiry for verification of the questionable location or other particular is promptly sent out.

At this point it should be noted that the size of bergs seen at sea at a distance of 2 or more miles is very deceptive. There is usually nothing of known size near them with which they can be compared. The patrol itself has frequently seen bergs that appeared to all on the bridge to be very large pinnacled ice masses when they were near the horizon, but which, when closely approached, proved to be rather insignificant, rising less than 30 feet above the sea and being less than 100 feet in diameter. So it is that bergs in the frequently bright smooth waters of the southern ice sectors, though reported as "large" and "very large," are often found when reached to be in fact quite small. They were probably sighted on the horizon line when nearly abeam of the reporting vessel, which had never closely approached and examined them because of the loss of valuable time that this would have involved.

The unusually large refraction values often found near the junction of the warm and cold waters makes the identification of bergs difficult and adds to the uncertainty when determining berg sizes from a distance. Sometimes bergs not over 30 feet high can be seen for 20 to 30 sea miles from a height of eye of 20 feet. Once during the 1929

ice season on a day when refraction was making objects loom up higher than usual the white ice-patrol vessel was reported to herself as a berg by a steamer that was observed to be passing by at a distance of approximately 10 miles.

However, if after a careful inspection no flaw in an incoming iceberg or temperature report is apparent, it must be accepted as correct and plotted on the cruise chart. The plotted bergs always have the date of the report written near by so that their successive positions from day to day can be followed. The water temperature values are plotted in different colored inks, the colors being changed every few days to enable the special portion of the cruise period during which they were received to be readily seen.

The water-temperature values and the ice, but especially the latter, are never looked upon as something fixed and unmoving. They are constantly regarded as though in motion, and from the moment they are plotted they are looked at with a continually questioning attitude. Where will they be and how much will they be changed in one, two, or more days? If the patrol is to be of high value to shipping this attitude is necessary. Bergs often have to be found several days after they have been reported, as at the end of a period of fog, or after the patrol has been released by the complete melting of a particularly dangerous berg that was being watched. Constant estimates must be made of berg positions at the expiration of different time intervals. The patrol has time to search out only the most probable locations of reported bergs. In most cases, due to the normal prevalence of strong currents, it can afford to go directly toward the spot where a berg was last sighted or reported only when the information is extremely recent, say, less than one day old.

The task of keeping track of the southern ice limits would be fairly simple if good visibility were as prevalent over the Labrador Current as it is over the Gulf Stream 180 miles south of the Tail of the Banks. As it is, the patrol has to keep up a constant matching of its wits against fog-shrouded currents. Its errors and successes are strongly brought home as its searches during daylight periods of good visibility are successful or fruitless. There is a constant stimulus to find new ways of predicting berg movements and to perfect the old, not so much for the information of shipping, but for the guidance of the ice searches of the patrol vessels themselves.

As the bergs are little affected by the wind, their movements are mostly controlled by ocean currents. Therefore, any method of predicting ice movements entails finding out the drift of water at the time. The present state of knowledge regarding ocean physics about the Grand Banks makes it appear that hydrodynamic surveys are the best means for determining the oceanic circulation there. The ice patrol has studied and worked with dynamic oceanographic

methods for some years. It has been found that the making of satisfactory surveys of this sort entails steaming over large areas frequently, for the precise surface and subsurface information that must be obtained can only be gathered by the patrol vessels themselves. With only one ice patrol vessel out on duty at one time this interferes greatly with the normal conduct of the practical part of the service.

The second-best method of determining currents and berg drifts about the Grand Banks is the interpreting of surface isotherm curves in the light of past experience. The cooperation from shipping that has been worked up enables the patrol vessel to plot the surface isotherms over a large area. The requirements of the hydrodynamic method and the dependence which can be placed on the surface isotherms are both discussed in the next chapter.

Conditions under which the patrol vessels work vary from month to month and from year to year. Weather conditions and information about ice coming in by radio often make it wise for the patrol to alter its course of action several times during even a single day. No hard-and-fast rules can ever be laid down, but existing circumstances, as viewed in the light of the patrol's past experience, must always determine the cruising and other activities of the patrol vessels on each cruise. As a general principle, however, it can be said that the patrol must leave for other vessels to find and report all ice east of the forty-seventh meridian and north of the forty-fourth parallel. To narrow down and simplify the problem still further, it can be stated that the patrol vessels should almost exclusively confine their own activities to the area of an equilateral triangle with sides about 175 sea miles long and corners near 41° 30′ N., 47° 00′ W., 41° 30′ N., 51° 00′ W., and 44° 48′ N., 48° 00′ W.

The above triangle contains about 13,200 square sea miles, and so is of the order of size that theoretically can be searched for ice two times during each patrol cruise. The areas along the western and southern edges of this triangle are most critical and should never be left unguarded for more than a very few days at a time, even during light ice periods. The reason for this is because the general drift of ice is southward down the western part of the triangle, then eastward along the westbound B steamship tracks near the southern part of it, and, finally, northward and northeastward away from the southern tracks and across the eastern side of the triangle.

A berg entering the circulation at the northern apex of the critical triangle, if it is not melted, shunted off by local currents, or held up by some means such as grounding or coming into an eddy, can easily be discharged into a very dangerous position right along the westbound B tracks within a period of from 10 to 15 days. Fog and strong currents and the necessity for standing by the most dangerous bergs, whether they are inside or outside of the critical triangle, make the

actual proper patroling of even the critical western and southern parts of its 13,200 square sea miles a continual problem.

During heavy ice periods about the only times when the area inside of this triangle should be left are when bergs that must be followed drift west or south of its southern portion. Of course during very light-ice times, which occur near the ends of some seasons, it sometimes happens that there is no ice in the critical triangle. Then occasional runs to the north can be made in order to locate the southernmost ice limits. Generally speaking, however, throughout the active ice-patrol season, if a high degree of safety from danger of collision with ice is to be maintained during times of low visibility along the B tracks, the western and southern portions of the critical triangle must be constantly and repeatedly searched. The ice found there must be most carefully watched and followed until it either melts or recurves and drifts so far to the north that it no longer menaces the B tracks.

During most of the ice-patrol season the B tracks just south of the critical triangle are in constant use. That means the route of westbound traffic to the United States lies right along the southern edge of the critical triangle. These westbound ships are of great assistance in reporting water temperatures and in notifying the patrol of chance bergs that may be crossing the southern part of the triangle for points farther south, with some drift of cold water. The eastbound B tracks are 60 geographical miles south of the westbound ones, and so are considerably safer than the latter, on the general proposition that the farther south of the Tail of the Banks one is in the ocean, in the long run, the fewer bergs will be encountered. The eastbound traffic is doubly protected from liability of meeting unreported ice by the active operations of the westbound ships in cooperating with the patrol.

Nevertheless, the 60 miles separating the eastbound and westbound traffic streams of the B tracks can be traversed by a berg during certain times of accelerated circulation in a period of about 30 hours. Therefore, especially toward the ends of periods of fog of two or more days' duration, even along the eastbound B tracks, vessels while between 52° W. and 45° W. are subject to a real, though very slight, chance of unexpectedly meeting an unreported iceberg. Because of the much greater danger along the westbound B tracks, however, the ice patrol must at all times exert its utmost efforts to locate all bergs that are approaching the latter lanes from the north.

Freighters, tankers, and other vessels not carrying passengers are not included in any track agreement and are not expected to adhere to any definite lane. A large number of the bolder vessels of the non-passenger class cross the ocean about where they see fit. The reports from such sources are the main dependence of the patrol for its knowl-

edge of by far the largest part of the great area lying between the United States and the Canadian tracks. This area is large when the patrol season starts, but it becomes very much larger as the advance of the spring melts back the field ice and permits the Canadian tracks to be shifted farther and farther north. It goes without saying that the value to the patrol of temperature and ice reports from vessels crossing between the usual tracks is inestimable. A large gain would be effected by the ice-patrol service if all such vessels would report their positions and water temperatures regularly instead of remaining silent unless they see ice, as it appears a number of them still do.

Those passenger vessels which cut to the north of the tracks that are in effect (and the patrol noted, in 1929, 100 different cases where vessels carrying passengers were 20 miles or more north of their prescribed lanes), if they do not take rigid extra precautions, decrease their chances of coming through the ice regions safely. Their masters should bear in mind the fact that the ice-patrol broadcasts do not necessarily list all the icebergs in any area, but only the icebergs of which the patrol and the reporting vessels have knowledge. The positions of ice in the broadcasts are always subject to a certain amount of observational error in the first place, and they become less and less reliable as time goes on, due to the impossibility of accurately forecasting berg drifts. Hope to make absolute determinations of future berg drifts can be expected neither from construction of dynamic current maps nor isotherm and ice charts. The best that can ever be hoped for is some reasonable approximation of the most probable courses and rates of movement that given bergs will take.

South of the Tail of the Banks reported positions of bergs, even if correct within a mile to begin with, are normally subject to a 24-sea-mile radius of error with every day that passes from the time of the last report of them. Occasionally swift currents cause the radius of error to reach 48 sea miles daily, and very exceptionally to approach 72 sea miles per day. The dates given with the positions of the southernmost bergs enable the recipients of the broadcasts to determine within 24 hours the time the different bergs were last reported or sighted. This permits their making a very rough approximation of probable berg locations when knowledge of the usual drifts of ice is at hand.

Some passenger liners, both eastbound and westbound, maintain notoriously high rates of speed, such as 20 knots, more or less, according to ability, even during periods of fog and darkness. The ice patrol has noted that a few of them actually maintain such speeds during bad visibility conditions when they are 100 miles and more north of their proper tracks. Such action is extremely foolhardy and is bound to result sooner or later in disaster.

Vessels maintaining high speeds southeast of the Grand Banks, as well as in more northern parts of the ice-patrol area, are at times dependent for safety on their chances of having an ice-free track ahead of them. It is entirely idle to think that microthermographs, subsurface echo or listening devices, or any other instruments that have as yet been developed by science, can protect ships from collision with ice if they are traveling at from 10 to 24 knots during dense fog, pitch darkness, and the like. If any device for detecting the presence ahead of bergs or heavy field ice were practical the fine steamers on the Canadian tracks would adopt it and proceed at reasonable speeds during bad conditions of visibility instead of stopping or groping along at about 3 knots, as many of them do at such times, while between the longitudes where icebergs are situated.

The danger of collision with ice is a real and not a fancied one at many times and places south of the Cape Race tracks and even south of the Tail. The *Titanic* is far from being the only vessel to have struck a berg. To mention two recent cases, the reader is reminded of the *Montrose*, which in 1928 and the *Vimeita*, which in 1929, struck bergs head on off the eastern edge of the Grand Banks. Neither vessel was lost, but heavy damage was sustained in both cases. No one should deceive himself in this matter. To depend blindly on the broadcasts of the ice patrol is not enough. The only way to be sure of not hitting ice in regions where bergs are liable to exist is to keep a bright lookout and to travel at speeds low enough to insure ability to stop or turn aside before striking a berg just visible ahead under the prevailing atmospheric conditions.

The Western North Atlantic can be likened to a great dance hall and the bergs to dancers. The southern part of the room is warm and unoccupied. The cold northern part of it is where the orchestra of the wind holds sway. There the floor is crowded by jostling dancers through whom one must pick one's way with great care. The central part of the room is occupied at times by a few of the hardiest and swiftest performers. Their maneuvers are watched, but the floor is vast and the light is so bad that fully half the time they can not be seen. Sending vessels past the Tail at high speeds during low visibility is like rolling thin glass balls across the central part of such a dance floor and hoping that they will not strike the flying feet of the dancers that occasionally execute intricate figures in the middle of the hall.

For postulated berg sizes and frequencies the mathematical chances of collision with ice under the worst conditions of high speed and low visibility can easily be calculated. Let us suppose that bergs 300 feet in diameter are ahead of a fast liner and that there is only one such berg along each 60 mile front at right angles to the course line. It very frequently happens that the southernmost bergs have not been

sighted for 24 hours because of fog. A berg may move north, though the flow of the main body of the Labrador Current more often makes it move south. If it goes south very rapidly under the above conditions of berg distribution the chances are good that the next berg to the north will take its place in the 60 mile section immediately ahead of the ship. In 24 hours the position of each berg south of the Tail may be assumed to be indeterminate by about 30 sea miles. What is the chance that ice will be hit?

The breadth of the liner can be neglected, for her maneuvering powers may be such that she can avoid a berg sighted ahead by half the amount of her beam, though if not properly made use of these same maneuvering powers are capable of causing a long raking collision when otherwise the vessel would have just passed clear. The chance that a berg will be hit works out at 1 chance in 1,200, the ratio between the 300-foot diameter of the bergs and the 60-mile front at right angles to the course line along which each berg was assumed to lie.

Such chances are not desperate ones, and they would doubtless be welcomed by trans-Atlantic fliers; but the aspect becomes different when it is considered that there are exceedingly many steamship crossings past the Tail during fog and darkness each season and that when bergs are far south they are likely to be spaced much closer than one to every 60 sea miles at right angles to the track.

Frequent long periods of fog make it impossible to guarantee that occasionally unannounced bergs will not get upon the B tracks. Whether or not there will be disastrous collisions with ice in the North Atlantic depends largely on the speed at which vessels run during thick weather and darkness while they are east, south, and southwest of the Tail. Ships crossing north of the Tail are, as has already been said, liable to meet more and more icebergs in proportion as they cross the Labrador Current in higher and higher latitudes; but their masters realize this and generally run very slowly during low visibility, thereby minimizing the chances of serious damage in the cases where they find collision with ice is unavoidable.

The above all serves to place some of the problems of the patrol before the reader and shows the inherent danger that lies in neglecting the scouting program for any purpose at all, even that of attempting to make current maps by the hydrodynamic method. So long as there is only one vessel out on patrol at a time, oceanographic stations can be taken here and there without any appreciable interference with the practical program, and this should certainly be done to keep up the annual continuity of the records of salinity and temperature offshore about the Grand Banks. Much useful information and much training in physical oceanography that may be valuable in the future, is given by the occasional scattered stations; but such station

arrangement only gives fragmentary dynamic information, and most assuredly does not permit the making of current maps of a sort that can be used as the basis for confident prediction of berg drifts.

The Convention for the Safety of Life at Sea that was held in London in 1929 took up the matter of the ice patrol and recommended that a maximum of three instead of two ships be made available for the work. It is hoped that in the future it will be possible to employ a third vessel whose complement will include a professional oceanographer. The ice-scouting and information-broadcasting vessels could then be relieved of the burden of the larger part, at least, of the scientific oceanographic work.

The addition of a vessel primarily for the scientific program would mean a great step forward and would be justified even if the dynamic current maps which it could make should finally prove to be of small practical value. In addition to the large funds of knowledge that such a ship should be able to obtain for pure science in such fields as oceanic circulation and submarine bottom configuration, her presence about the Grand Banks under the direction of the commander, International Ice Patrol, would at critical times be of great practical value. She could send in surface temperature and weather conditions reports to the scouting ship from areas from which no ships were reporting and could be called upon when necessity arose to search key areas or to trail and observe the final disintegration of especially dangerous bergs.

The main patrol vessels, on the other hand, when relieved of the oceanographic station work could better take on board the necessary additional personnel and gear to permit a start to be made in the matter of ice scouting by aircraft from the patrol vessels. The cautious and well-thought-out use of aircraft to assist during periods of fine weather in searching out the region in and near the critical triangular area just north of the B tracks would seem to be one of the most promising of the fields of development that are open to the ice patrol at the present time.

OCEANOGRAPHY

1. Scientific work during the 1929 patrol season.
2. Prediction of iceberg drifts.
    A. Surface isotherms as basis for prediction.
    B. Dynamic current maps as basis for prediction.
3. Estimate of total annual amount of glacial ice south of forty-eighth parallel and its total chilling effect on the water.
4. Observations on iceberg disintegration south of the forty-fourth parallel.
5. Possibility of breaking up icebergs artificially.
6. Local convectional circulation about icebergs.
7. Miscellaneous.

1. SCIENTIFIC WORK DURING THE 1929 PATROL SEASON

Following immediately after this chapter the reader will find figures showing a number of current diagrams and oceanographic sections constructed from data obtained at some of the 69 oceanographic stations occupied during the season. That portion of the year's stations too isolated either in time or place to be utilized for the construction of current diagrams or sections are of scientific interest as records of 1929 surface and subsurface temperatures and salinities in the vicinity of the Tail of the Grand Banks. Therefore, all station data are given in full at the end of this pamphlet.

Station procedure in general and the normal levels to be sampled were the same in 1929 as since 1925. The main advantage in adhering to the same levels year after year is that the values found are then strictly and easily comparable over long periods of time. Uncorrected Richter and Wiese reversing thermometers without attached auxiliary thermometers were used in Greene-Bigelow water bottles at all stations. The variable-speed electric hoists used at the stations were equipped with spooling devices that laid up the $\frac{5}{32}$-inch steel wire on the drums satisfactorily. The hoists gave good service without any interruptions and there was no loss of gear.

One of the ice patrol's two electrical salinity determining cabinets having worn out, the use of a titrating outfit for the *Modoc* was obtained through the courtesy of Harvard University. This method of determining salinities, new for the ice patrol, was purposely set up and tried out during rough weather early in the season. It was found perfectly workable when due precautions were taken to handle the delicate glass instruments with care and to protect them by the use of suitable racks and string ties.

The electrical salinity measuring method as used on the ice-patrol vessels is about twice as fast as the titration method and is much easier and simpler; hence it should be used when a very large number

of water samples are to be handled. The comparative cheapness, light weight, and availability of the titrating outfits, however, make them preferable to the electric-salinity cabinets, unless over 1,000 samples of water are to be analyzed per ship per season. The former are from twenty-five to fifty times cheaper and lighter than the electrical outfits. For worth-while results both methods require well-trained and conscientious operators. Under comparable conditions the accuracies obtainable by the two methods are probably about equal.

The large number of bergs south of the forty-eighth parallel during the 1929 ice season claimed the patrol's almost undivided attention. If the ice had been less, either in extent or amount, more oceanographic work would have been done. In a general way, and as in previous years, the currents that the dynamic oceanographic computations showed theoretically should exist, actually did exist in fact, as shown by occasional iceberg and patrol-ship drifts.

2. POSSIBILITY OF PREDICTING ICEBERG DRIFTS

A. SURFACE ISOTHERMS AS BASIS FOR PREDICTION

Berg-drift predictions are highly necessary for the information and guidance of the patrol itself, even though the conclusions should not be accurate enough to send out in the broadcasts. Therefore, any method simpler than the dynamic one that the patrol ships could employ without interfering too much with their primary scouting and trailing duties is much to be desired. Having explained at some length in the preceding chapter the features of some of the problems confronting the ice patrol, the matter of predicting berg drifts can now be taken up with clearer understanding.

The only other method besides dynamic mapping that has been suggested for picturing the varying circulation in the ice-patrol area has been that based on a study of surface isotherm charts. The surface isotherms have always been assumed to give a broad general idea of the prevailing water and ice movements in and about the Labrador Current throughout the season. The main reason why the patrol vessel carefully plots both her own surface-temperature observations and those coming in from other ships is because the ice in general is expected to be found and to remain where the water is coldest.

The cruise isotherm charts have been considered valuable enough to reproduce each year in the ice patrol's bulletins, but they have not been given important consideration when attempting to forecast movements of bergs that have not been sighted or reported for some time. The reason for this lack of confidence lies in the numerous discrepancies that have been noted when bergs did not move parallel to the isotherms or even close to the direction which the surface isotherms seemed to indicate they should take.

It is obvious that if it were possible to deduce from a study of the surface temperatures alone the circulation existing at the time, and that is likely to continue to exist for some time to come, the making of estimations of future berg drifts would be rather simple. Experience shows that with the cooperation of passing vessels isotherm charts can be constructed every 15 days which show in excellent detail the picture of surface temperatures over almost the whole of the region between the thirty-ninth and forty-ninth parallels and the forty-third and fifth-sixth meridians. This embraces all of the usual ice regions south of Newfoundland and a goodly area of their surrounding waters as well. It covers an area between ten and twenty times as large as that which two ships of the character of the present ice-patrol vessels could keep properly mapped dynamically in the eddying waters about the Grand Banks, even if they devoted alternating at-sea periods entirely to oceanography.

The making of the isotherm charts from the ship's log and from the received radiograms is a routine process that requires but one or two hours of work per day from two men. It does not consume any of the ship's scouting time or interfere with any other of her ice-patrol duties, and so is entirely within the capabilities of the present ice patrol. On the other hand, the full projection of dynamic current maps is not, as will be shown in the next section.

The vital question is whether the best surface isotherm charts procurable can be interpreted in any way to be relied upon to properly picture the circulation of the layers of water which control the movements of the bergs. Hardly less important is another query: If the true circulation at the instant is mirrored properly, how much can the surface isotherms be depended upon to tell the story of what currents will prevail from two to seven days later?

The first thing that must be done when approaching the problem is to determine what paths icebergs have taken in the past. The main courses that they are likely to follow in the southern part of the Labrador Current are very clearly shown in Figure 30 on page 69 of Coast Guard Bulletin 16. This chart, which sums up the berg-drift information gathered by the ice patrol up to and through the 1927 season, is one of the fundamental sources of practical ice-drift information. It is constantly referred to when bergs are reported or sighted because it gives some information of the direction in which the ice may drift while not under surveillance. This chart and its companion chart, Figure 29 on the page facing it, when compared with the composite picture obtained from a study of all the isotherm charts explain why it has been assumed that the bergs tend to remain in the colder waters and to follow in general the usual paths taken by the varying pushes of the same.

Even when the case is narrowed down from full seasons and cruise periods to that of individual drifts it is still found that a good agreement is actually observable between many berg, wreckage, and ship drifts, on the one hand, and the particular distribution of current that the surface isotherms at the time suggest, on the other. This raises grounds for hope that an intelligent interpretation of the isotherm curves alone can be used to forecast future berg drifts, at least in some regions and cases.

Let us examine the isotherm and ice charts of the 1928 and 1929 ice-patrol seasons and see how much the isotherm charts in their present state of development can be depended upon to indicate berg drifts. The charts should be considered with the usual drifts of bergs about the Grand Banks in mind and with a knowledge of the general subsurface conditions of the region that the oceanographic station work to date has furnished. To depend upon the different isotherm charts alone would be to invite confusion and misinterpretation.

Some of the rapid berg drifts indicated by dotted lines south of the forty-third parallel on the ice charts for the months of May and June, 1928, show a general agreement with the isotherm chart for the period during which they occurred, May 21 to June 5, 1928. Comparison of three drifts shown on Figures 9 and 10 with the isotherms on Figure 28 in Coast Guard Bulletin No. 17 suffices to show this. The berg drifts during the period of the seventh and eighth patrol cruises of 1929, from July 3 to August 2, again illustrate the good correlation between the surface isotherms and the regional oceanic circulation in the area of special danger to shipping south and southeast of the Tail. To facilitate comparison the drift tracks of all of the 1929 bergs whose drifts the patrol was able to determine have been placed on the respective isotherm charts appearing in this Coast Guard Bulletin.

From the comparatively pure Gulf Stream waters just to the south of the limits of bergs many temperature reports are received by the patrol. These waters are found to be often characterized by deep embayment of the isotherms, similar to those that occur in the colder mixed waters just offshore of the Tail. Coming in with the temperature reports from the waters of tropical character there are frequent reports of spars, buoys, and other floating objects. Attention is called to the particular drift of a buoy shown on the isotherm chart for the period June 18–July 2, 1929. This buoy's drift was plotted from a series of reports each so complete and specific as to positively identify it. There were no strong breezes or gales to interfere with the local currents. It can be seen that its successive positions indicate that the local drift among the isotherm embayments in the warm water was at the time to the northwestward,

very much at variance with the ordinary conception of the flow of the Gulf Stream drift but in direct agreement with the direction of drift which would have been predicted from an inspection of the local surface isotherms on the chart.

But watching the drift of bergs and other passively floating bodies is not the only available means of ascertaining local currents. The moderate wind conditions that usually prevail in the ice-patrol area during the last half of the patrol season enable that portion of the patrol ship's own drift which is due to current alone to be rather accurately determined during times of good visibility.

The value of current determinations of this sort varies with the accuracy with which the vessel's observations of the heavenly bodies are made. Methods of position fixing by means of soundings and radio bearings, though at all times useful for check purposes, and necessarily relied upon during foggy and overcast weather, are not exact enough to be of much use for accurately determining ocean currents off the Tail of the Grand Banks. On the other hand, the positions obtainable through celo-navigational methods during favorable periods are at times dependable within a radius of not over 3 miles, and so quite valuable for this purpose.

Position fixing is of prime importance to the ice patrol for a number of reasons and great attention is paid to it. The most modern methods of handling the observational and chart work are followed. Positions are checked by independent work of at least two experienced navigators.

Spending most of its time searching relatively small areas near the temperature wall between the Gulf Stream and the Labrador Current, drifting at night, and keeping track of its position as it does, it is believed that the ice patrol is at many times particularly capable of observing the rates and directions of the local currents. Many of these currents are so restricted in size and vary so much in direction over the course of one or two hundred miles that they are frequently averaged out and lost during the long runs made daily by ships bound east and west across the ocean at speeds exceeding 8 or 10 knots.

In three cases when the ship's location was well determined strong currents were observed during the 1929 ice-patrol season, as follows: On April 25 and 26, a sustained 2.6-knot current setting east and northeast along the forty-second parallel between 49° W. and 51° W. On June 7, a current setting southeast over 2 knots near 41° 38′ N., 48° 56′ W. On June 24 and 25, a 2-knot easterly current near 42° N., 50° W. In every case the existence of these strong currents is fully indicated by the position of the curves on the isotherm charts. When a well-developed cold wall exists between the Gulf Stream and Labrador Current a rapid flow parallel to the isotherms seems to be characteristic.

One of the striking features shown by the surface isotherms southeast of the Banks is that of the tremendous embayments in the boundary between the cold and warm currents. That the warm and cold tongues are especially well developed in the middle part of the ice season is shown by the isotherm chart for the period May 21–June 5, 1928 (fig. 28 in Coast Guard Bulletin 17), and the one for the period June 3–18, 1929 (fig. 29 in this pamphlet).

Very often where an extra cold tongue from the Labrador Current extends southward on the surface an extra warm tongue will protrude north close to it and just to the westward, it would seem almost as a compensation. This sharp contrast of waters at times appears to accelerate the local oceanic circulation along the adjacent intensified temperature walls. The 5-day drift of 160 miles across the forty-fifth parallel of the southeasternmost berg of April, 1928, is not in close agreement with the surface isotherm indications in the area, but it is quite characteristic, and may be typical of the local area and the particular contemporary distribution of surface temperature. The writer believes it to be referrable to the close approximation of tongues of 42° and 54° surface water near 44° 20′ N., 45° 50′ W., which are plotted on the isotherm chart for the period April 6–21, 1928 (fig. 25, Coast Guard Bulletin 17).

Examples of berg drifts much at variance with the surface isotherm indications are easily found. Off Cape Race, along the eastern edge of the Grand Banks and close to and west of the Tail, such apparently anomalous berg drifts are frequent. Possible explanation of this condition can be found in the persistent streaming along of the layers of cold water controlling the bergs. It appears as though the cold water is at times forced under warmer and lighter surface layers, and in these cases the surface isotherms should not be taken as guides for berg drifts. To be able to detect these cases experience in the ice-patrol region or close study of the old ice-patrol records is necessary.

Before any definite statement can be made it will be necessary to determine more fully under what conditions and how regularly surface isotherm curves can be assumed to mirror the underlying circulation. Present indications are that this is the case and that valuable information can be obtained from them in the cases where and when a cold wall is strongly developed. By a cold wall is meant a region in which the surface isotherms are noticeably packed. It is a narrow belt across which the surface temperature gradient is much greater than it is farther on in either direction along the line drawn at right angles to the different isotherm curves.

The dynamic investigations have shown that the density wall, which usually controls the circulation, normally lies a variable distance inshore of the cold wall in the Grand Banks area. When depending on the surface temperatures alone the exact location of

the density wall is, of course, unknown. Nevertheless, in cases where a cold wall is strongly developed, it appears that the following rule holds good. An observer stationed along the junction line between markedly warmer and colder water, will, if he faces directly toward the cold water and puts the warm water at his back, have the local ocean current in his immediate vicinity, both behind and before him, flowing from his left-hand side toward his right-hand side.

This is not advanced as any general rule for the Northern Hemisphere or even as an infallible one for use in the whole of the 150,000 square sea mile most probable ice area about the Grand Banks. At some times and in some places the varying relations between different water masses are affected by earth rotation, winds, shoals, and other factors too much for that. There are complications caused by shifting of surface and subsurface layers from their original positions, and masking effects due in place to late season surface warming over true cold water. Nevertheless, the rule is a good working one for the ice patrol when it is used with due regard for the special dynamic and other circulation conditions that are liable to be encountered.

When the horizontal surface temperature gradient is small, and in the localities liable to subsurface pushes of cold water the case is not clear. Nevertheless, the surface isotherm charts are already of such great value to the patrol for the estimation of berg drifts that every effort should be made to improve their character, regardless of whether or not the dynamic oceanographic maps are continued.

It is certain that the isothermal method is susceptible of greatly increased development, mainly through increasing the number of incoming water-temperature reports. Such an increase in number would be very desirable even if the values were not useful for constructing surface isotherm charts. These reports serve to keep a close check on the positions and courses of the different passing vessels, inform the patrol what areas are being searched for ice, and tell what weather conditions are prevailing in different localities.

An average of 60 water temperature reports per day were received during the 1929 ice season. If this could be increased to 100 reports per day the value of the isotherms for estimating currents and berg drifts would be more than doubled. The value of the isotherm charts would be greatly increased by a few more reports per day if these could be obtained from vessels crossing the ocean between the United States and the Canadian tracks. Requests for water temperatures from this area are often inserted in the broadcasts in order to obtain more values from the little-frequented parts of it. An increase in the total number of temperature reports and a little better distribution of them would permit the making of a valuable isotherm chart weekly instead of every 15 days and would also permit a slight

reduction in the temperature interval between some of the isothermal lines.

Any final general statement at this time of the value of the isothermal method of determining ocean currents in the Grand Banks region would be premature, however. The whole matter of correlating berg drifts and surface isotherms is now under critical study. The drifts of bergs during the 1930 ice season will be closely watched for instances of their adherence or nonadherence to the isothermal indications. They should furnish considerable additional data upon which to judge the merits of the case.

B. DYNAMIC CURRENT MAPS AS BASIS FOR PREDICTION

Another method, distinct from the examination of surface isotherm curves by experienced observers, has been suggested for prediction of iceberg movements. It involves the construction of dynamic current maps, and is undoubtedly accurate when certain conditions are fulfilled. To make good current maps of this kind, however, a more detailed dynamic mapping of the area is necessary than the ice patrol can usually undertake. Therefore, under the present conditions it is impossible to get the maximum obtainable amount of benefit from this method.

How an exact knowlege of the temperatures and salinities prevailing at the different levels throughtout an area permits the construction of a current map showing the local oceanic circulation has been fully explained in the Coast Guard bulletins describing the ice patrols of 1926, 1927, and 1928. Coast Guard Bulletin 14, December, 1925, gives detailed information telling how such maps can be made and interpreted. Some idea of the effort which the ice patrol must put forth to do satisfactory dynamic oceanographic work will be obtained from the discussion which follows.

Because of rapid mixture of warm Gulf Stream and cold Labrador Current water, the ocean currents off the Tail and the eastern slope of the Grand Banks are in a particularly active state of turmoil and fluctuation. Therefore, to be sufficiently comparable, dynamically, to give satisfactory current maps, the different oceanographic stations within an area about 100 geographical miles square must be occupied during a period of not over 10 days. The results would be more reliable and lasting if the stations were taken within a period of seven days. To confine the station work to an area smaller than 100 sea miles square, or to an equivalent rectangle of less than 10,000 square geographical miles, would be to limit so seriously the scope over which the berg-drift predictions could be made as to make the current map of very small practical value.

The time during which the taking of a series of stations can be safely spread out will vary much with the rate of change of location of the different water masses in the area under observation. The

7 to 10 day periods mentioned above represent the estimated time lapse which the writer considers permissible for a set of observations taken under the usual conditions that prevail in the various 10,000 square geographical mile areas located over the deep water just east and southeast of the Grand Banks.

A case of shift of position of water masses due to time lapse can be seen when stations 1078 and 1091 are compared. These were occupied within 10 miles of each other, but the interval of 21 days between them prevents a reasonable dynamic comparison of the two water columns. In the period between the taking of the first and second of these stations a lighter water column appears to have pushed inshore toward the eastern edge of the Banks. The warming of the surface layer can be attributed to seasonal effects, but this cause can not explain the large temperature rise of the 125 and 50 meter levels. The salinities at all levels above 750 meters are much alike at the two stations. The considerable difference in temperature values at some levels can best be explained by postulating an inshore invasion of warm water.

Fifty stations, taken within the stipulated 7 to 10 day period, are about the minimum number that can give a current map of a 10,000 square sea-mile area of sufficient accuracy to be of much real practical value to the ice patrol. From the experience of the past four years it is known that 50 stations, arranged in five rows 20 miles apart, with 10 stations in each row spaced at intervals averaging 10 miles, would suffice to give a dynamic current map showing in some detail the complicated local currents of a 100 sea-mile square area.

When completed, the dynamic current maps are interpreted much like weather maps, but the stations must be placed much closer together than the Weather Bureau's observing stations if the complicated detail of the water circulation is to be caught. They must be spaced much closer about the Grand Banks region than similar oceanographic stations taken for like purposes in parts of the ocean where erratic currents due to mixture of radically different water masses are absent.

The hydrographic station values need not be regathered so frequently as meteorological observations at weather stations. It is well that this is so because it is much more tedious and difficult to get the required dynamic data properly at an oceanographic station than it is to observe the meteorological elements at an ordinary Weather Bureau station. The great mobility of the atmosphere requires the weather map to be remade from the synoptic data every 12 hours and in the sea off the Grand Banks where the currents are especially complicated and interlocking, the stations must be taken, as stated previously, within a 7 to 10 day period and comparatively close together to get the full story of the sea-water inter-

actions. Because the current speed and the mobility of the ocean swirls are of the order of twenty to forty times less than that of those in the atmosphere, the current maps when once made are probably good for about one week, though it is doubtful if the detailed current map of the hypothetical 10,000 square sea-mile area made during the course of 7 to 10 days, can be depended on very closely after three or four days from its completion, due to the length of time required to develop it.

Taking the most favorable arrangement of courses possible, to make a good useful current map of the 100 sea-mile square area with 50 stations as outlined above, it is necessary to steam about 600 sea-miles. At 8 knots, a high average speed for a scientific ship to maintain under the conditions prevailing about the Grand Banks, this would take 75 hours. Add 50 hours to this for the time required for work at the 50 stations, and a period of 125 hours, or just over five and one-sixth days, of intensive undivided work by a ship in midocean is seen to be necessary to gather the data required for the making of a dynamic current map of what is really a very small portion of the usual ice area south of the forty-eighth parallel.

During a large part of the station taking period good visibility should prevail, for it is very necessary to insure accurate geographical location of at least a number of the stations to keep the whole map from being hazy and indefinite. In places near the edge of the Banks radio bearings and sonic soundings serve to locate position rather accurately at times, but in most places many and good celo-navigational observations are absolutely essential to satisfactory position fixing. Observations can only be obtained during weather excellent for ice searching.

If the very exacting oceanographic work inseparable from the construction of detailed dynamic current maps is seriously prosecuted, the primary object of the patrol, the location by scouting and radio information of ice for the protection of shipping, must be neglected to an appreciable extent. Each time, before commencing upon the cruising necessary to the construction of a current map, the commanding officer of the patrol ship must weigh the possible advantages to be obtained from a dynamic current map against all features inimical to the practical program that such construction will entail. A current map made at the expense of a vessel's disastrous collision with ice which might have been averted, but for the oceanographic work, would involve a cost entirely too high to pay. A single patrol ship can either make current maps or stay with the ice. It can not do both at the same time with any degree of justice to either.

Apart from their practical value to the ice patrol, dynamic current maps have a permanent scientific value which is not interfered with by delay in plotting them. A number of current maps in the Grand

Banks region have already been made, however, and it would seem to be established that they can be made, and that they can be made again whenever necessity arises. A close study of maps already on hand would now seem to be in order, rather than a multiplication of maps of very transient value to the patrol.

During very light ice years, and at times when all the bergs are 200 miles or so to the north of the steamship tracks being used between Europe and the United States, an ice patrol with one vessel only out on duty might be justified in devoting itself to the tasks of dynamic oceanography to the extent of attempting to make detailed current maps of 10,000 square sea mile areas. Even during such times, however, such a procedure is open to question. When the Europe-United States tracks are not endangered by ice it would seem to be but logical to devote attention to actual patrolling along the southernmost routes between Canada and Europe. The ice patrol, besides being international in name, is entirely so in fact, receiving its support from international contributions, and therefore bound to protect impartially to the limit of its ability all the ice-endangered tracks across the North Atlantic.

Putting aside this possible exception during light ice years and periods, it would certainly seem that the ice-patrol service as now conducted, that is with two ships alternately out on duty, should most emphatically not devote its activities to oceanography to the extent required for the construction of good dynamic current maps. Depending upon poor current maps is worse than not having any at all. The real solution of the dynamic mapping problem lies in the employment for the ice-patrol duty of an additional vessel, charged primarily with the scientific work.

3. ESTIMATE OF TOTAL ANNUAL AMOUNT OF GLACIAL ICE SOUTH OF FORTY-EIGHTH PARALLEL, AND ITS TOTAL CHILLING EFFECT ON THE WATER

It has been argued by a certain school of scientific thought, influenced by the oceanographer, O. Petterson, that the bergs about the Grand Banks in melting furnish the energy which keeps the southern reaches of the Labrador Current moving along as they do. On the other hand, others, and especially F. Nansen, contend that melting icebergs have little effect in producing great ocean currents.

Attempts to estimate the total amount of glacial ice that comes south of the forty-eighth parallel in any one year and to consider its possible chilling effect on the water masses there may throw some light on this problem. If it is a fact that a negligible amount of cold water is produced by the melting of the bergs that get south of the forty-eighth parallel in the Labrador Current, it will be reasonable to suppose that their melting will be unable to have much effect on the hori-

zontal ocean currents that exist to the east and south of the Grand Banks plateau.

In 1929, the heaviest ice year that the international ice patrol has experienced to date, approximately 1,300 bergs drifted south of the forty-eighth parallel in the Western North Atlantic. When it crosses the forty-eighth parallel the cubical contents of the average berg, above water, is not greater than that of a block of ice 100 feet high, 400 feet long, and 100 feet wide. That means that the average berg has, above water, not more than 4,000,000 cubic feet of glacier ice. Lieut. Commander Edward H. Smith, a former ice-observation officer of the patrol, estimates the average above-water volume of bergs about the Grand Banks to be one-third of this amount. However, a certain amount of glacial ice in the form of growlers crosses the forty-eighth parallel each year. To allow for this ice, and to insure that the total quantity of fresh-water ice will not be underestimated, a rather larger average size has been allowed for the bergs than would otherwise be the case.

It is quite likely that a fair estimate of the correct annual total amount of above-water glacial ice that enters the region about the Grand Banks will be obtained by multiplying the total number of bergs given by the ice patrol as south of the forty-eighth parallel each year by 4,000,000 cubic feet. This figure is advanced as a maximum one, the real amount being probably somewhat smaller, due mainly to duplication of berg reports.

The total amount of ice to come south of the forty-eighth parallel is, of course, the sum of that which is above and below the sea surface. The underwater body of a berg being quite irregular and largely hidden, its total volume is extremely hard to determine by actual observation or measurement. In the past it has undoubtedly been overestimated. The fresh-water glacial ice of the North Atlantic iceberg is, according to experiments made by the physicist, H. T. Barnes, about 10 per cent lighter than the solid ice which is formed on the surfaces of lakes and streams in winter. The reason for its lightness is found in the much larger proportion of air in the form of tiny bubbles that it contains. All the pictures of ice in this bulletin show how white and clouded with innumerable tiny air bubbles the glacial ice of icebergs really is. According to Barnes' estimate its specific gravity averages close to 0.830 as compared with about 0.916 for clear ice and 1.000 for pure water at the point of maximum density.

Since nearly all of the bergs to the south of latitude 48° N. float in sea water of density varying between 1.02 and 1.03, they must float on the average about one-fifth out of water instead of one-eighth. Until recently the latter figure has commonly been accepted as approximately correct, but if Barnes is right, it is entirely too small.

The actual range of density of glacial ice in the Grand Banks region should be checked by more observations.

The size of the average berg has been taken great enough to insure that no large underestimation can be introduced into the final figures by the slight uncertainty that still exists relative to the average specific gravity of the ice. Therefore, multiplying the average berg's 4 million cubic feet of above water ice by five, we find that on entering the waters about the Grand Banks it contains not over 20 million cubic feet of ice in all, or, in other words, has a total mass slightly in excess of 500,000 short tons.

The total amount of berg ice, both above and below water, south of the forty-eighth parallel in 1929, may, therefore, be estimated as thirteen hundred times 20 million or 26 billion cubic feet, which is roughly about 676 million short tons. Such an amount of ice would require well over 100 trillion British thermal units to reduce it to water at 32° F. This is a formidable amount of heat, for each British thermal unit is equal to 252 gram calories.

It is with this draft of heat that icebergs melting south of the forty-eighth parallel directly affect the temperature of the waters in which they are distributed. As soon as the area in which the 26 billion cubic feet of ice melts is estimated, the possible effects on water layers in the area can be computed.

The isotherm and ice maps show that the cold waters that would be directly affected by this melting ice extend over about 20,000 square sea miles south of the Tail, 30,000 square sea miles along the eastern edge of the Banks, and 24,000 square sea miles between the forty-seventh and forty-eighth parallels. (See figure 1.) This is a total area of 74,000 square sea miles or 2,644 billion square feet.

Hereafter this area will be referred to as the "melting area." The section of it to the south of the Tail, and the southern half of the section of it along the eastern edge of the Banks, include the whole of the 13,200 square sea-mile critical triangle of the patrol described in the chapter on procedure and remarks. They include the waters that surround the critical triangle as well. The northern parts of the "melting area" include all waters through which the bergs pass to reach the critical triangle.

It was also stated in the discssion of the practical problems of the patrol that berg ice is normally found each year inside a 150,000 square sea-mile area south of the forty-eighth parallel. The "melting area" is the very heart of this usual ice area, and inside of it fully 90 per cent of the ice that comes south of the forty-eighth parallel can be expected to melt. To draw comparisons so that the size of the "melting area" can be more readily visualized, its 74,000 square sea-mile extent is a little larger than the six States that comprise

New England, and a little smaller than the combined area of England and Scotland.

Without attempting to discuss the vertical circulation that takes place within the radius of a mile or so from a berg melting under the varying weather and water conditions that it encounters during its life span in the Grand Banks region, it is certain that the bergs do chill sea water there in melting. It makes no difference in a discussion of their total chilling effect whether they affect surface or subsurface layers. From whatever stratum the heat is chiefly drawn, the total amount consumed will be the same.

Let us assume that the bergs directly affect a layer of water averaging over the 74,000 square sea-mile "melting area" 50 feet thick. This is a minimum thickness to expect them to affect and a convenient one for calculations. It gives 133,200 billion cubic feet of water in the "melting area" to be affected by the disintegration of the total of 26 billion cubic feet of glacial ice. Simplifying the problem, it is found that for each 5,123 cubic feet of water there is 1 cubic foot of ice.

The latter is very close to 32° F. in temperature when it crosses the forty-eighth parallel. Neglecting the lightness of the glacial ice, and the salinity of the sea water, and generously allowing that 80 cubic feet of the latter can be chilled 1° F. by the melting of 1 cubic foot of the ice, it follows that the melting of the total amount of glacial ice present throughout the whole ice season in the region under discussion would only counteract the normal seasonal warming of a 50-foot layer of water in the melting area south of the forty-eighth parallel by 0.0156° F., an insignificant amount.

It should be borne in mind that the 1929 ice year, on which the 26 billion cubic-foot berg ice total used above is based, was an ice year about three times as heavy as the normal one. It is safe to say that during the normal year, when less than 400 bergs come south of the forty-eighth parallel, supplying the heat requirements of the glacial ice disintegrating in the "melting area" does not chill any 50-foot stratum of water in the cold current there by more than 0.01° F.

It has been assumed in arriving at the above estimate that no chilling effect from the bergs is lost directly to the air. This loss exists, but it is doubtless extremely small. It has been further assumed that no locally ice-chilled water is lost from the "melting area" to the westward past Cape Race, to the westward to form bottom water over the Grand Banks, or to the southeastward past Flemish Cap. Analysis of berg drifts shows that, during the ice season at least, there is but little push of cold water to the westward past Cape Race or onto the Banks. Some losses in these directions occur, however, and even more ice and cold water are lost to the southeastward past Flemish Cap. The sum total of losses in all three directions probably amounts

to well over 5 per cent of the effect of the melting bergs. The larger this percentage loss is, the less will be the chilling effect on the local waters of the bergs that melt in the "melting area."

The 0.01° F. figure is a maximum for still another reason not previously brought out. During a 100-day ice-patrol season, the cold current is entirely renewed at least once throughout the "melting area" if the average southerly drift of the current is only 4 sea miles per day. But the southerly drift of the ice bearing waters averages much more rapid than this. Therefore, the chilling effect of the season's bergs should not be figured upon the simple extent of the 74,000 square sea miles. It should be spread out over a water volume covering a surface more than twice as large, over the total area of cold water that passes through the "melting area" during the ice season.

These conditions need not be emphasized because the approximate figure of 0.01° F. which was arrived at is already sufficiently small to indicate the relative unimportance of the bergs as chilling agents in the southern reaches of the Labrador Current. Even if very large miscalculations have crept in, and the total amount of berg ice to get south of the forty-eighth parallel should by any chance be twice as large as has been estimated, still its effects will be so small as to make them extremely unimportant.

An oceanic effect diametrically opposite to the chilling influence of melting bergs is to be found in the vernal warming at and near the surface about the Grand Banks. The next paragraphs will discuss that part of the tremendous seasonal warming which the ice patrol is able to observe, and will compare its magnitude with the 0.01° F. chilling value just deduced.

The normal ice-patrol season can be taken as 100 days long, from March 25 to July 3. A slight amount of exterpolation is necessary to arrive at the March 25 and July 3 surface temperature values in years when the active patrol season begins late or ends unusually early. On the whole such allowances are easy to make and the ice-patrol period can be used as a convenient measuring stick.

Since the normal ice-patrol season extends from just past the vernal equinox to well past the time of the sun's most northerly declination, the sun has a high position in the heavens at noon, and the surface waters warm up rapidly over the whole Grand Banks regions throughout the time. Although there are large local variations, and also annual variations of less amount but larger significance, comparison of the patrol's surface isotherm charts show that the rates and amounts of warming in the same areas in different years agree closely.

At the beginning of the season, just before April 1, the temperature of the Grand Banks surface water is about 33° F. At the close of the season, a little after July 1, it is about 55° F., a rise of 22° F. Over the varying extent of cold Arctic stream water south of the Tail, the

temperature is about 33° F. at the start of the season and 50° F. at its close, a rise of 17° F. Along the eastern edge of the Banks the true cold water rises from about 32° F. to about 47° F., a rise of 15° F. Between the forty-seventh and forty-eighth parallels the Labrador Current surface water during the same time warms from about 32° F. to about 44° F., a rise of 12° F. South of the Banks along the fortieth parallel in the Gulf Stream the rise during a 100-day ice-patrol season amounts to 10° F., from about 60° to 70° F.

The varying rates of warming in different areas about the Grand Banks are in the main easily accounted for. The Grand Banks water, for instance, is shoal and it is somewhat less subject to fog blankets than the Labrador Current. Moreover it is relatively stationary in so far as the effects of true ocean currents, as distinct from tidal ones, are concerned. It is, therefore, favorably situated to show a high degree of vernal surface warming.

On the other hand, the surface water of the southern parts of the Labrador Current is constantly being replenished by cold water from the north. It is underlaid by extremely cold water and overlaid by much fog throughout the season. The effects of solar warming show up slowly and it is easy to see why it only warms up 14⅔° F. on the average during the time in which the Grand Banks surface waters are warming up 22° F.

The Gulf Stream's small surface warming despite much clear weather can be attributed principally to the fact that its waters are already warm. It is flowing with a large northerly component into cooler regions of decreased sun strength where radiation and other losses can with less and less facility be counterbalanced.

The area of mixed surface water between the Gulf Stream and the Labrador Current changes position and size rapidly, varying so much from month to month and year to year that it is hard to say just what its exact increase in temperature is. A fair figure would be one somewhere between that of the pure Labrador Current and Gulf Stream surface water, say 13° F.

Coming back to the 74,000 square sea mile "melting area" it can be seen that, though principally over the Labrador Current, it slightly overlaps the Banks, and extensively overlaps the mixed water offshore. Fourteen degrees Fahrenheit can be taken as a good figure for the total rise of its surface water temperatures during the 100-day ice-patrol season. The warmed waters tend, of course, to remain near the surface of the sea, hence the warming effect decreases rapidly with depth throughout the Grand Banks region.

Let us assume that the rise of temperature at the 50-foot level in the "melting area" during the ice-patrol season is 10° F., as compared with 14° F. at the surface during the same time. The stations which the ice patrol has taken in the area usually sample the surface, the 25-

meter, and lower levels, and tell nothing directly about the temperature of the 50-foot level. Nevertheless, a study of temperature curves made from the station figures shows that 10° F. is a conservative estimate to make for the average increase in temperature at the 50-foot level between March 25 and July 3.

Let us neglect the tremendous sum total warming that takes place in decreasing increments in the 50-foot layers of water below the 50-foot layer that has its upper boundary at the surface of the sea. We can for the purpose of this discussion simply assume that the total effect of solar warming from March 25 to July 4 is not less than enough to warm all the water from the surface down to the 50-foot level in the "melting area" an average amount of 12° F.

Now a rise of 12° F. in 100 days means that the average rise is 0.12° F. per day. It has been shown that 0.01° F. is a very generous amount to allow for the chilling effect of a full season's bergs south of the forty-eighth parallel on a 50-foot layer of the "melting area." One one-hundredths degree Fahrenheit is only one-twelfth as much as the average daily rise of 0.12° F. In other words the total chilling effect of bergs in the "melting area" is not sufficient to nullify more than two hours of the average vernal warming effect that is active throughout the ice-patrol season.

This seems hard to believe at first when one looks at the ice charts of the ice patrol. It must be kept in mind that the bergs marked on these charts must be large enough to be plainly seen. As drawn they are far too big in proportion to their proper scale size. The real amount of glacial ice south of the forty-eighth parallel each year is comparatively small when considered in relation to water volumes of 50-foot layers of the "melting area."

One way to get a conception of the relative smallness of the 26 billion cubic feet of glacial ice that came south of 48° N. during the heavy 1929 ice season is to assume it to be spread out evenly over the surface of the "melting area," of 74,000 square miles, or 2,664 billion square feet. The whole season's bergs spread out at once would make a uniform layer of glacial ice only about 0.01 foot, or one-eighth inch thick.

A skim of ice only one-eighth inch thick would not be expected to last long or to interfere much with vernal warming of a fresh-water lake. It should be expected to last far less time and to interfere with warming no more over the "melting area." On second thought the comparatively negligible effect of the bergs south of the forty-eighth parallel on the water masses there is seen to be quite plausible.

It is recognized that none of the variables that have been considered in arriving at the conclusions reached in this section are accurately known. Therefore, the results can be only approximate and can only serve to give an idea of the orders of magnitude involved. In cases

of doubt large values have been taken to arrive at the chilling effects of the bergs, and extremely small values to arrive at the total effect of vernal warming. For this reason the estimate that the melting of bergs south of the forty-eighth parallel offsets the solar warming effect in the "melting area" by but two hours is likely to be much too large. The true time figure is probably less than one hour. But even if gross errors have crept in and the two hours should be 100 per cent too small instead of too large, the negligible effects of the melting bergs in the southern parts of the Labrador Current would still be apparent.

If the bergs melting south of the forty-eighth parallel do not make and keep the southern reaches of the Labrador Current cold and active, then what does? The answer to this question leads very far afield and can not be more than hinted at here.

Barnes [1] sees the source of the cold water layers in the Gulf of St. Lawrence and southeast of Newfoundland in the melting of icebergs. Lieut. Commander Edward H. Smith, United States Coast Guard, has stated in the course of conversation with the writer that, because of their large size and immense numbers, the melting of bergs north of the forty-eighth parallel has a much more powerful effect than that of bergs melting in the "melting area." The sum total of the berg effects, in his opinion, amounts to almost nothing, however. It is many times exceeded by that of melting northern field ice. He further stated that the combined effects of both bergs and field ice were entirely inadequate to account for the enormous volume of cold water that is discharged annually past Labrador by the Labrador Current. He contends that its true source must be looked for in direct winter chilling of the sea in northern regions by the air.

He bases his opinion on a critical study of all the important oceanographic and explorational work that has been undertaken in the North Atlantic and polar basins, as well as on the results of his own work while with the ice patrol and the Marion Expedition. The latter scientific expedition into the waters between Greenland and Labrador, it will be remembered, was sponsored by the United States Coast Guard for the benefit of the scientific program of the ice patrol in 1928. The results of its work have not yet been fully published, but will be issued from time to time as special numbers in the series of Coast Guard bulletins. Lieutenant Commander Smith has just finished his discussion of ice and currents, and these sections, embodying his views, a few of which are briefly outlined above, should appear at an early date.

It is believed that the calculations of chilling and warming effects made in this section will help in a small way to support the Nansen idea of oceanic circulation as interpreted by Lieut. Commander Edward H. Smith.

4. OBSERVATIONS ON ICEBERG DISINTEGRATION SOUTH OF THE FORTY-FOURTH PARALLEL

One might assume that the ice patrol as now conducted has more frequent and better opportunities actually to observe the disintegration of icebergs and field ice than is the fact. There are some opportunities for first-hand observation, of course, but these are often not so good as might be wished. For instance, during the writer's four years' experience with the ice patrol he has never seen a single square foot of the field ice that is so abundant during the early season in the northern parts of the Grand Banks region. The reason for this is that the patrol must almost always remain close by the southernmost ice limits. About these limits the field ice is not usually found, and even the bergs themselves are rather few and far between.

Frequently after a day of searching a berg reported earlier by a passing vessel is found late in the afternoon after the completion of a predetermined search pattern. It is usually given a berth of from one-half to one-fourth mile, though sometimes it is passed closer, depending upon weather and other conditions. The ship will then be stopped 1 or 2 miles to leeward of the berg, where it is "secured" for the night—that is, steam is turned off the propelling machinery and the larger generators and auxiliaries, to save fuel for future searches for ice.

When daylight returns next morning the berg is usually only a small white mass on the horizon. It may even be 8 or 10 miles to windward, on account of the relatively greater effect of breezes on the ship and surface water than on the deep-lying berg. It may be approached again before the new day's search is started, but in many cases it is only relocated from a distance by a series of bearings taken with the aid of the gyrocompass repeaters on the wings of the bridge. Such bearings can locate the geographical position of the berg as well as steaming up to it, and they can be taken while the ship is running along on a set of courses planned to make the new day's search for ice most effective.

Possibly the patrol will return to the old berg for the night, and if this is done, a comparison can be made with the way the ice looked 24 hours earlier. But new bergs that require watching may be found in more threatening positions than the old one, and if this is the case, the former may never be seen again.

Each season a few of the most southern bergs are watched during a period of days. Then the usual procedure is to drift well clear of the ice and to run up toward it once or twice a day, in the evening, or both morning and evening, depending on the rate at which the patrol ship is drifted or blown away.

During about one-third of the ice-patrol season fog makes all continued observations of ice impossible. Bergs under surveillance when

a long period of fog shuts down are invariably lost. After a protracted foggy spell the patrol does its most intensive cruising, trying to relocate the new positions of the dangerous bergs.

Each year a certain amount of time is lost in futile searching for bergs reported from extra southerly locations. These bergs frequently can not be found because of the strong currents and rapid ice disintegration, which obtain in the warm surface waters along the northern edge of the Gulf Stream.

Besides the rather limited opportunities for close first-hand observation, the varying shapes of the bergs themselves, and the varying conditions of wave motion and water temperature about them, all go to make the subject of berg disintegration a complicated and conjectural one. The determination of the life of a berg that is sighted south of the Tail of the Banks is certainly not obtainable through the application of any hard and fast rules.

Obviously 130,000 tons of ice in the form of growlers and small pieces will melt much faster than the same amount of ice in the form of a single solid berg. Not only will the smaller pieces have a greater total area exposed to water action, but they will be entirely in the upper layers of water that are warmer and more affected by wave motion than the layers that are 50 feet and more below the surface. The pieces of ice that calve from a berg nearly always stream off to leeward, under the influence of winds, waves, and surface currents. They rapidly melt and disappear and the life of the parent berg is undoubtedly materially shortened by continued prolific calving. Some of the bergs, because of their peculiar shape and particular internal structure, or the unusual conditions of water and weather that they experience, calve more than others.

The fresh ice exposed when a piece falls from a berg south of the forty-fourth parallel is dry and frosty at first. The spot, even though far above the reach of sea and spray, soon becomes wet, however, and so it generally remains. After long exposure the upper parts of bergs sometimes become rough and granular and apparently dry, while between the granules they may be wet in fact.

Barnes [2] states that bergs calve most near sunrise and that they dry up and freeze on account of radiation from their surfaces at night. This may be true of bergs north of the Grand Banks, but that it is true of bergs melting in the warmer southern portions of the "melting area" south of the forty-fourth parallel should not be assumed without more direct evidence. On the contrary, the late afternoons, nights, and early mornings are foggy or cloudy more than 50 per cent of the time during the ice season in the southern parts of the "melting area." Such conditions are not conducive to effective nocturnal chilling of berg surfaces by radiation and keep as well the early rays

[2] H. T. Barnes, "Thermit and Icebergs." Journal of the Franklin Institute, May, 1927.

of the sun from striking the ice. During 1929 one berg southeast of the Tail approached on a cloudy night was seen when the beams of a searchlight were played on it to be pouring off water from all visible surfaces, just as so usually happens during the day.

Notwithstanding the need for further observation and study, the observations which the ice patrol has been able to make to date permit some conclusions to be drawn about the life of bergs south of the forty-fourth parallel. Two late instances will be given.

A berg of not less than 500,000 short tons mass was seen by the patrol for the first time on July 17, 1929, about 55 miles south-southeast of the Tail. It was in water close to 60° F. at the surface at this time and remained in such water throughout the remainder of its life. It disappeared entirely late on July 26, nine days after it had been first sighted. The berg was a rather solid one and this disintegration was considered quite rapid. A berg of about the same size in 1928 lasted south of the Tail from May 21 to June 4, a period of 14 days. The time was earlier in the season and the water was considerably colder during most of this time. In fact, it was in surface water colder than 38° F. from May 21 to May 25. Both of the above bergs were larger than the average berg that gets below the forty-fourth parallel, being of the approximate size of the generously large berg taken in section 3 of this chapter as the average size which crosses the forty-eighth parallel.

The experience of the ice patrol all goes to show that in the 50° to 60° surface water south and east of the Grand Banks the average berg can be counted on under all ordinary circumstances to be entirely melted in from 7 to 10 days. Only extremely large and resistant bergs are able to survive longer in water warmer than 50° F.

It was computed in the section of this chapter dealing with glacial ice totals that the abnormally heavy 1929 ice season provided only enough ice south of the forty-eighth parallel to cover the "melting area" of 74,000 square sea miles with a film of ice one-eighth inch thick. The only reason why the glacial ice reaches so much lower latitudes and persists south of the forty-eighth parallel each season two to three months longer than the field ice does is because of its concentration in the large masses known as icebergs. If it were not so concentrated it would vanish overnight and never reach the 50° and 60° water east and south of the Banks.

The field ice so prevalent during the first third of the ice patrol season in the northern half of the "melting area" and in the regions to the north of that, has an enormous preservative influence on the bergs. If there were no field ice off the Labrador and Newfoundland coasts in the winter and spring there would be far less of a berg problem along the trans-Atlantic tracks than there now is. The field ice has been credited with acting as a fender which keeps the

bergs during certain months from grounding along the North American coast north of Cape Race, and so eliminating themselves from southern waters. Whether this be true or not, it is an undeniable fact that the field ice tends to keep the surface water about it ice cold. A berg surrounded by field ice in the Labrador Current until it is south of the forty-fifth parallel is conserved much as a cargo of meat is conserved in a refrigerating vessel that is steaming through the Tropics.

But the field ice prolongs the life of the bergs in another way than through its great cooling effect. In addition it effectually prevents the development of wave motion, and in this way protects most efficiently the vulnerable waterlines of bergs from the washing and melting attacks of moving surface water.

Calving most frequently takes place by the dropping down of ice masses that overhang an undercut water line, and so is closely related to surface water attacks. Calving upwards from the smoothly rounded underwater portions of a berg is exceptional in the ice patrol regions. Sometimes a projecting spur that is mostly submerged is broken off by stresses arising from the rise and fall of the swell. These stresses are very large at times, and so are the blows of the sea against a berg's sides. Bergs are usually very dead in the water and take the full force of the seas like rocks. They do not normally roll or ride over the seas like well-designed ships do when drifting.

Calving generally involves but a very small portion of the mass of a berg at any one time. Of course bergs sometimes break up into two nearly equal parts, but in fully 90 per cent of the cases the amount of ice involved in a calving is so small in comparison with the mass of the berg that equilibrium is only slightly affected. This is the case, even when the meaning of calving is restricted to production of ice volumes of more than 1 ton. The breaking off of small pieces is very frequent under some conditions, and this production of small amounts of ice in the form of chips and tiny blocks is not considered real calving, such as is contemplated here.

It is reasonable to suppose that the chances of calving and rolling will be much greater in warm water than in cold, but it must be remembered that the conditions will vary much with each individual berg. To venture an opinion for the benefit of those who in the future may be called upon to work upon bergs for any purpose, it is estimated that the average berg south of the forty-fourth parallel can be expected to have natural calvings involving the falling off of over 1 ton of ice about three times a day, and to experience changes of position involving the turning about an axis more than 60° in less than one minute of time about twice a week. The above is only a rough estimate, based on comparatively few observations. Some bergs will not calve for days at a time and will never turn over until

they have been reduced to the size of a ship's boat. Other bergs will both calve and roll about much more than the average.

The varying water temperatures in which a berg may be floating have a great effect on its speed of disintegration, but it is doubtful if the percentage of the total wastage due to calving, compared with that due to direct melting from the berg, varies much under any conditions met south of the forty-fourth or even the forty-eighth parallel. The effects of calving are more noticeable in some cases than others, however. For instance several bergs seen near the Tail in 1929 had water lines showing that the upper parts of the berg were rising higher and higher out of the water. They were very few in number, and they may be explained by excessive calving, or by floating in very cold sub surface water during periods of warm bright weather that were especially destructive to large portions of their above-water bodies.

Nevertheless, despite low temperatures of surface water at all places during the early season, and in many places until close to the end of the ice period, and despite permanent low temperatures at the lower levels reached by bergs in the "melting area," the constant effect of the sea water moving about in intimate contact with the water line and the great underwater surfaces of bergs must be the most important factor working toward their destruction. Subaerial melting from the bergs is a minor factor, but still it adds its quota to the melting process of berg disintegration, as distinct from the loss of mass through calving. Over the whole ice-patrol area the sum total calving effect is probably much less than the total surface melting effect in getting rid of the bergs.

From a small boat that pulled about a berg which pitched heavily while calving on July 15, many air bubbles were seen to be rising through the smooth water and breaking at the surface within a dozen feet or so of the vertical ice walls of one side. Some of these bubbles appeared to be nearly 1 inch in diameter and these made a considerable disturbance at the surface like the large bubbles of marsh gas that rise through shallow waters under certain conditions. Each of the larger bubbles of gas in the case of the berg were undoubtedly made up from the combined contents of many of the formerly imprisoned tiny air bubbles of the glacier ice. The separate air bubbles in the bergs are generally less than one-thirty-second of an inch in diameter, much smaller in size than the head of an ordinary common pin. The particular berg of this instance was floating in surface water of temperature 57° F. The continuous coming up of air around it is good evidence of the rapid underwater wastage which occurs whenever the water is that warm.

When movement of the slight swell exposed portions of ice below the average water line of the above berg it was seen that the under-

water surfaces were not smooth, but dimpled. This condition was undoubtedly due to differential melting about the individual glacier grains. This dimpled effect is almost always noticeable when the water lines of bergs are closely inspected. Perhaps the underwater bodies of bergs while melting about the Grand Banks, though smoothed and rounded in general outline, may all be composed when the detail is considered of these roughened surfaces. They can be compared to nothing so well as to magnified "goose-flesh" with the intervals between the individual projections or the individual hollows of the order of about half an inch.

To mention a few more examples of berg disintegration observed during the 1929 season it can be stated that on the afternoon of July 24 the ice patrol was standing by a berg in 61° water 55 miles south-southeast of the Tail. The berg was seen to calve heavily. In a few minutes a boat put out from the patrol ship with a swimming party and a number of the growlers in the vicinity of the berg were boarded.

This could be easily be done, either from the boat or the water, without much discomfort, for the chilling effects of the ice on the surface water could be noted on ordinary ship's hold water thermometers only when within a few yards from some of the berg's ice walls, and when the boat was in the midst of a group of growlers spaced on the average 50 feet or less apart. In a few such places temperatures 58° F., but 3° lower than the general sea surface of the neighborhood, were recorded.

About the berg that pitched when calving on July 15 slightly greater local depression of surface temperature was noted. This berg, as already stated, was surrounded by sea water of 57° F. temperature at the surface. In one direction only from this berg was any chilling noted, but a depression of over 1° F. extended on this side to about one-fourth mile from the ice. Close to the berg the sea was 54° to 52° F. at the surface on this chilled side, and here, inside an ice-bottomed, well-washed bay cut into the berg behind an outlying ice pinnacle the temperature was 50° F. Among some near-by growlers a minimum surface temperature of only 48° F. was found. On the other hand, unchilled 57° F. surface water was found close to the vertical walls of the berg on the side opposite to the chilled water and growlers. The weather was calm, warm, and clear, and there was only a slight swell.

5. POSSIBILITY OF BREAKING UP ICEBERGS ARTIFICIALLY

It has often been stated that noise or small blows can break up bergs. The firing of 6-pounder blanks and the sounding of the steam whistle and siren within 100 yards of unstable looking bergs has always failed to bring down any pieces of ice at all during the dozen or more instances in which the writer has seen it persistently tried. Even

PLATE XIV.—Firing explosive 6-pounder shells into the high thin wall forming one side of a dry-dock type of berg. In this instance a number of tons of cracked ice were brought down into the sea. July 11, 1929, latitude 41° 34′ N., longitude 49° 00′ W.

PLATE XV.—Two officers from the *Modoc* on a large growler that an hour earlier formed a projecting ledge just below the water line of a near-by berg. This ice was entirely melted within 24 hours, 61-degree water, July 24, 1929, latitude 42° 10′ N., longitude 49° 30′ W.

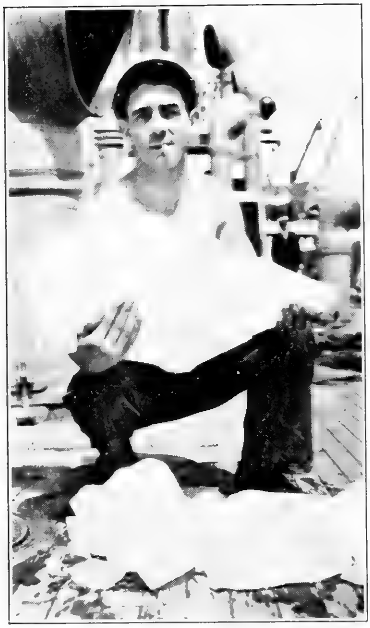

PLATE XVI.—Fragments of iceberg hoisted aboard. This ice is hard and homogeneous. Its opacity is due solely to great numbers of tiny spherical air bubbles

PLATE XVII.—Swimming close to an iceberg in 58° surface water. This ice is not in the Gulf Stream, but is in a great pool of Labrador current water that has been highly warmed at the surface by continued vernal warming. At 100 feet below the surface the temperature was less than 40° F. The striping on the sunlit berg wall directly behind the swimmers may be due to differential melting between annual layers accumulated on the ice cap of Greenland. Taken from ship's boat July 18, 1929, latitude 42° 28′ N., longitude 50° 05′ W.

overhanging and towering ice walls and cracked pinnacles seem unaffected by such noises. Six-pounder shells will bring down from a few pounds to a few tons of ice. They are most likely to produce damage if fired into weak portions of vertical or overhanging walls. Sometimes a lucky shot placed in a crack near a pinnacle or a corner about ready to fall will serve to produce a sizeable growler.

That a berg about the Grand Banks can be noticeably shattered or affected by any such thing as the making of noises near it, or by weak blows like those from an axe should be considered as conceivable, but verging upon the extreme height of improbability. The above statement is made in spite of the following experience with a seemingly fragile berg.

One day in August, 1928, the United States Guard Cutter *Marion* was run alongside a small grounded berg off the Labrador coast for the purpose of obtaining ice. While the berg was being attacked with an axe it calved and pieces of large size thundered into the sea, pushing the vessel well clear. The action of this berg was alarming and impressive to those witnessing it, but it should not be taken as showing the great liability of bergs to disintegrate because of small blows. As a matter of fact the ice that calved off amounted to very little when compared to the total mass of the berg. The parts that fell off were located along an almost vertical, slightly undercut wall. The ice was probably just about to come down of its own accord from the internally strained, grounded berg. It did so when the ship was gently bumped against it by the slight swell, and when the men on deck struck at the ice surface opposite them with an axe.

Because of the rapidity with which bergs break up themselves, and because of the known physical properties of ice, it has been suggested that the southernmost bergs be removed from the paths of navigation by boarding and mining them. Some experiments along these lines have been carried out in past years by the ice patrol, but without much success. There are on the average 51 bergs south of the forty-third parallel each year, and to attempt to mine any large proportion of them, even if feasible, would consume much valuable time that might be devoted to ice scouting.

It has already been shown that bergs in the warm waters south and east of the Grand Banks have a life span of only 7 to 10 days. The rapidity with which they break up from natural causes throws no little element of risk into mining operations on them. The conditions are brought out somewhat in the preceding section on ice disintegration, but to evaluate further the risks the next few paragraphs have been written for the benefit of future ice patrol officers who may be called upon to experiment again with the mining of bergs.

Some bergs are very delicately balanced. Two turned over during 1929 while being passed by the ice patrol vessel. It is hard to see

why a great piece of ice riding on the swell of the open ocean should turn over when struck by the almost imperceptible waves of a vessel passing 100 yards or more away at a speed of 10 knots, but that is what seemed to take place. Many bergs, even among the number of those that project like rounded cones and hills from the sea, are so finely balanced that they require but little to make them roll over. One small rounded berg that was boarded in 1927 from a small boat off the eastern edge of the Banks turned over half an hour after the boarding party had departed. One smoothly rounded 1929 berg that was watched for about a week southeast of the Tail was seen to roll over at least once a day without any noticeable calving or breaking up.

Assuming, however, that the situation appears to be favorable, and that it is decided to attempt to mine a berg, the first problem is to get upon it. Bergs too steep to be boarded without the aid of ropes can doubtless in some cases be solved by shooting lines over them, hauling stronger lines over their summits, and fastening floating weights such as log fenders to the end of the line opposite to the boarding party.

Spiked shoes are needed to keep from slipping, and axes for cutting footholds in the hard ice are essential if any steep slopes are to be ascended. The officer in charge of the boarding party must bear in mind that, to the ordinary small boat risks attendant on landing upon and getting picked up from a large uninhabited object in the open sea must be added the danger of immersion in cold water.

The actual cold water and boarding risks approach the vanishing point about bergs in smooth water over 50° F. at the surface. But whether a berg will calve or turn over while being approached or worked upon is hard to predict. The observations of the patrol show that calving south of the forty-fourth parallel is not generally confined to any particular time of the day but is liable to occur at any time. Turning over of a berg usually occupies a number of seconds, but it is liable to occur without warning, or only after the sudden warning of a heavy crackling and calving. Probably in most cases where a berg turns rapidly through 60° or more the boats attending the working party will have the duty of pulling their charges out of the water.

Even if all parts of the berg that have towering pinnacles are avoided, there is danger that a subsequent rolling movement will cause ice to slide down upon persons on a berg. A movement in the other direction would elevate the working party and put them in danger of dropping down over cliffs to ice shelves or down into the sea upon or among closely spaced growlers.

The most stable bergs on the whole are the tabular ones. A squad of infantry could be placed upon the tops of the largest of these bergs and drilled at both close and extended order with comparative safety. In 1929 the tabular bergs south of the forty-fourth parallel were

about as numerous as the thin-walled dry-dock type or the rounded water-worn type. The undulating top surface of the tabular bergs often appears to be but a very slightly modified form of the surface of the original glacier from which the ice was set free. From a short distance it appears to be composed of rough grains about the size of marbles and it is often muddied and soiled by the abundant bird life. Many of the tabular bergs have walls that are kept vertical throughout almost all of their life history in the Grand Banks area by calving off of overhanging pieces as the waves eat into the berg about the water line

On May 31 a tabular berg approximately 115 feet high and 400 feet square was seen near the Tail, and on July 15 another large berg, seen around noon 90 miles south-southeast of the Tail, was of a form bordering upon this type. At about 2 p. m. attention was called to the latter berg by a cry from the bridge. It was calving heavily and pitching as it did so. Whenever its sheer end walls became overhanging ones they gave way, and then the suddenly lightened end of the berg would lurch upwards. This caused the process to be repeated from the other end. The berg calved three or four times in this manner during the space of about a minute. It was not over 2 miles away and could be clearly seen at the time by those on the bridge and about the decks. Soon it became quiescent very close to its former position of trim.

6. LOCAL CONVECTIONAL CIRCULATION ABOUT ICEBERGS

Barnes[3] states that melting bergs draw in the surface waters toward them and that they have warmer surface water immediately about them than is the case farther away. It is quite possible that bergs do draw in, chill, and sink certain amounts of surface water under some conditions of melting. This might easily be concluded in view of the rather small surface temperature effects described in the section of this chapter on ice disintegration.

Nevertheless it is difficult to see from theoretical consideration how bergs can do much along the line of sinking chilled water in the "melting area" south of the forty-eighth parallel. During the ice-patrol season the surface water of the region is in general much warmer and somewhat fresher than the layers 25 and 50 meters down. Such conditions indicate a marked stability of the water column, and are directly opposed to the production of vertical convection currents.

In the early season many of the bergs keep in water that is below 32° F. at all levels about them until they are well south of the Tail. Of course, in the case of such conditions they can not cause much local circulation through chilling and sinking water that they draw in

[3] Annual Report of the Smithsonian Institution for 1912, p .737.

toward themselves because of the physical impossibility of anything chilling the already frigid water by more than 1° or 2°.

Throughout the year, just below the upper 25 or 50 meters of water throughout almost all the 74,000 square sea mile "melting area," the next layers of water remain, in general, very cold. At many stations 38° and 37° F. water is found just below the 25-meter level, even though the time may be June or July, and 50° to 55° F. water may be encountered at the surface.

Let us consider the conditions that prevailed in the upper portions of the water column at station 1085. That station was taken at 42° 01′ N., 49° 29′ W., about 3 miles east of a large berg, on July 18, 1929. The conditions there are listed below and are a bit more extreme than the average, but still they are rather typical of the melting conditions that surround nearly all the bergs that melt south of the forty-fourth parallel during the last half of the ice-patrol season.

Levels	Temperatures	Salinities
	°F.	Per mille
Surface	57.2	32.89
25 meters	39.7	33.31
50 meters	35.4	33.91
125 meters	37.0	34.42

It is evident from an inspection of the above figures that the berg because of the increasing salinity with depth, would be forced to chill the surface waters very much more than 21.8° F. in order to sink them down to the 50-meter level. The inevitable freshening of the waters while they are being chilled by the glacial ice would make it still harder for them to be sunk.

Let us neglect the great differences of salinities and the freshening effects and assume that the berg will chill the surface waters in immediate contact with it 20° F. and sink them to some depth located between the surface and 50 meters where they will find their new hydrostatic level. It is easy to calculate the approximate amount of water that can be chilled 20° F. by an individual berg of 130,000 short tons mass. Lieut. Commander Edward H. Smith estimates this to be the size of the average berg about the Grand Banks, so it can safely be taken as the average size of bergs in the southern half of this area south of the forty-fourth parallel.

If each pound of the ice can chill 80 pounds of water 1° F., a 260-million pound berg can chill approximately 1,040 million pounds of water 20° F. At 62½ pounds per cubic foot, the amount of water chilled 20° F. would be 16,640,000 cubic feet. Suppose the berg lasts out a full life-expectancy for surface water over 50° F. and continues to melt for 10 days. It will then sink daily, on the average, 1,664,000 cubic feet of water chilled 20° F.

Assuming that the sinking action attracts in toward the berg the surrounding surface waters down to the 10-foot level, what will be the rate of inflow of these surface layers? At the circumference of a circle of 1,000-foot radius from the center of the waterline plane of the berg the area of a 10-foot vertical section of the surface layers of water will be 62,832 square feet. A horizontal inflow of but 27 feet per day, which is only about 0.0002 knot, will more than suffice to supply 1,664,000 cubic feet of water daily through an opening of this size. By proportion it can be assumed that the inflow will amount to about 270 feet per day, or 0.002 knot, at a point close to the ice walls, but 100 feet from the center of the waterline plane of the berg.

The above figures are believed to give a very fair theoretical value for the order of magnitude of surface inflow that is possible about a berg melting in the Grand Banks region. The inflow is undoubtedly so small in value that differential drift of surface and subsurface layers, wind and wave effects, and other confusing elements, are easily capable of distorting and entirely masking most of the noticeable effects of such an inflow, if and when it exists. Even should the above approximations be in error by a factor of 10, still the inflow toward the most rapidly melting bergs would be extremely small.

It is now plain why growlers calved while breezes of any appreciable strength are blowing generally float away rapidly to leeward from a berg. Even those produced during periods of light airs and calms almost invariably move away, though on the average at much lower rates of speed. The maximum flow that the sinking of chilled water can cause apparently produces an inflow of surface water so small that it is nearly always masked by the other forces operating. If the inflow were at all large it would often be able to hold calved growlers and small pieces in positions alongside the parent berg.

Final conclusions regarding the local circulation, both vertical and horizontal, about bergs south of latitude 44° or 48° N. should not be drawn from theoretical considerations, however. Neither should they be formed from the results of a study of tank experiments or of the few actual observations about bergs that have been made to date. It is hoped that when opportunity offers the ice patrol will take numerous special oceanographic stations and make studies with variously colored stains placed in the water close to bergs during all sorts of weather and water conditions. What is now needed is a larger body of exact observational data upon which to base sound opinions.

Microthermographs have been suggested as instruments for warning ships of the proximity of ice during times of low visibility, but whether they will ever be of much practical value is still an open question and subject to grave doubt. The scientific observer of the international ice patrol should never be satisfied until after the detailed

100277—30——9

circulation about bergs under all conditions has been thoroughly investigated and is well understood.

7. MISCELLANEOUS

Detailed sounding and bottom sampling work about the Grand Banks region would be very useful, practically as well as scientifically. For the past five centuries the fishermen of France have been frequenting this area, yet even to-day the French scientists admit that they know almost nothing about the composition or detailed bottom configuration of the top or slopes of the Grand Banks plateau. Steam trawlers are annually increasing in numbers there. These vessels can not proceed haphazardly with their fishing like the old fashioned sailing vessels. Their costs prohibit hit or miss methods. They must know promptly where the greatest numbers of fish are located and where the bottom characteristics are not destructive to their expensive gear. Well coordinated scientific investigations are called for by the fisheries problems alone.

In 1927 one of the French Government ships attending the fishing fleet reported that three new shoals were situated less than 30 miles to the westward of the main track of bergs along the 1,000-fathom curve of the eastern slope of the Grand Banks. These shoals, though small, were said to have only 8 to 11 fathoms of water over them. Do they presage the birth of another low sandy island like that graveyard of the Atlantic, Sable Island, or will the water over them eventually be deepened by the waves of the open sea? Only continued soundings in their vicinity can tell.

On November 18, 1929, there occurred an earthquake centered in the sea south of Newfoundland. The shock was severe enough to be distinctly felt in the New England States, over 800 miles to the westward. Twelve cables crossing the area of greatest disturbance were broken in 23 places and the Burin Peninsula of Southern Newfoundland was visited by an earthquake wave. This wave was so large that much property and a number of lives were destroyed. Some geologists believe that the section of the ocean floor where the cable breaks occurred foundered during this earthquake. The ice-patrol ships will have a good opportunity to sound out the supposedly sunken area south-southeast of Cabot Strait with sonic depth finders, for they must cross it every time they proceed between the ice regions and their Nova Scotian base of supplies. If any great increase in depth over the form values exists, it should be detected when the new soundings are compared with the old ones that are already on the charts.

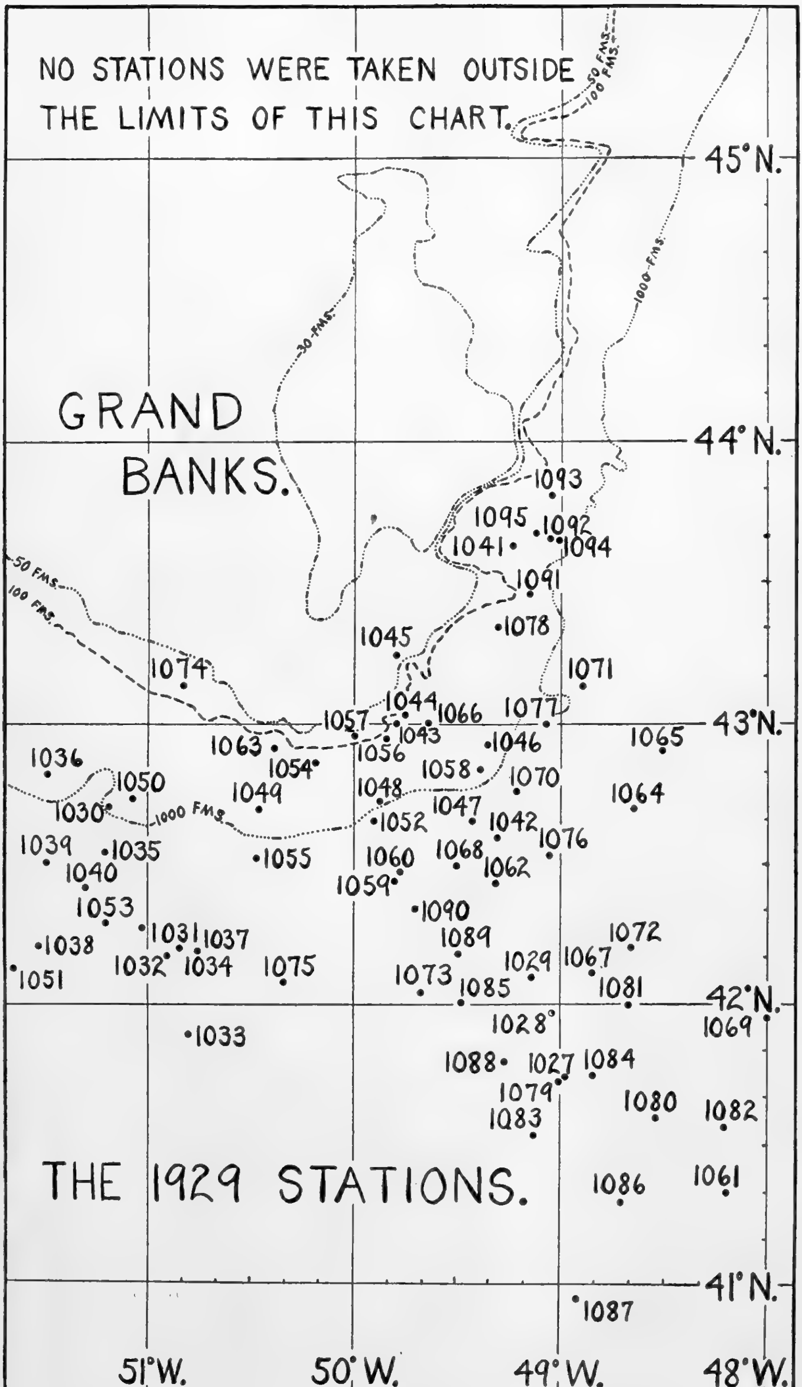

FIGURE 12.—Distribution of oceanographic stations

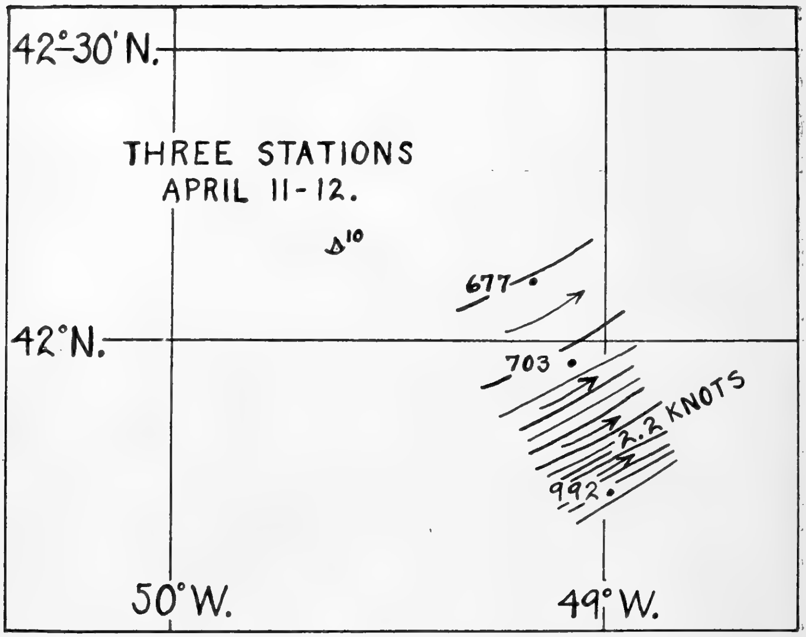

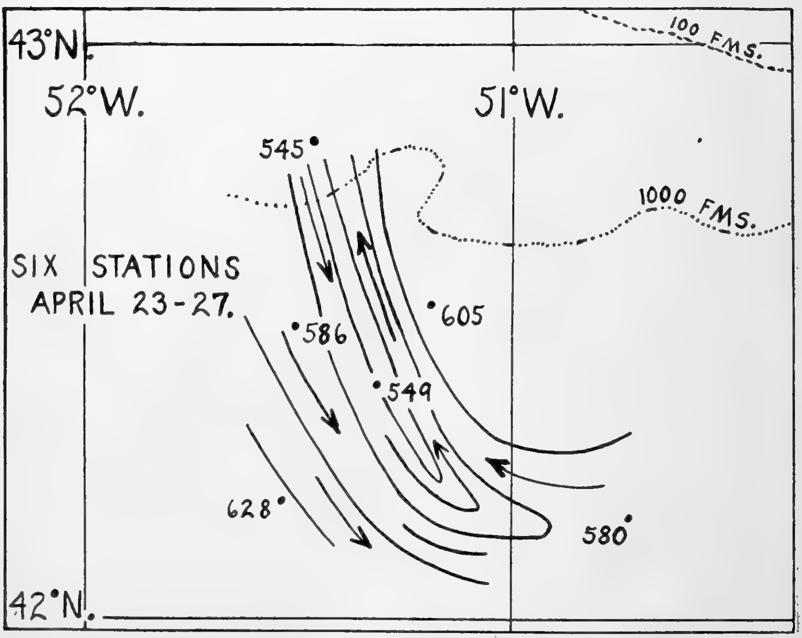

FIGURES 13 AND 14.—Two current maps constructed from two small groups of stations occupied during April, 1929. Three-figure numbers near stations show in dynamic millimeters distance in excess of 728 dynamic meters from sea surface to 750-decibar pressure level; 2.2-knot current indicated between two southeasternmost stations was computed from formulas in Coast Guard Bulletin No. 14. Currents of this magnitude are frequently experienced in reality near the temperature wall between Gulf Stream and Labrador Current waters

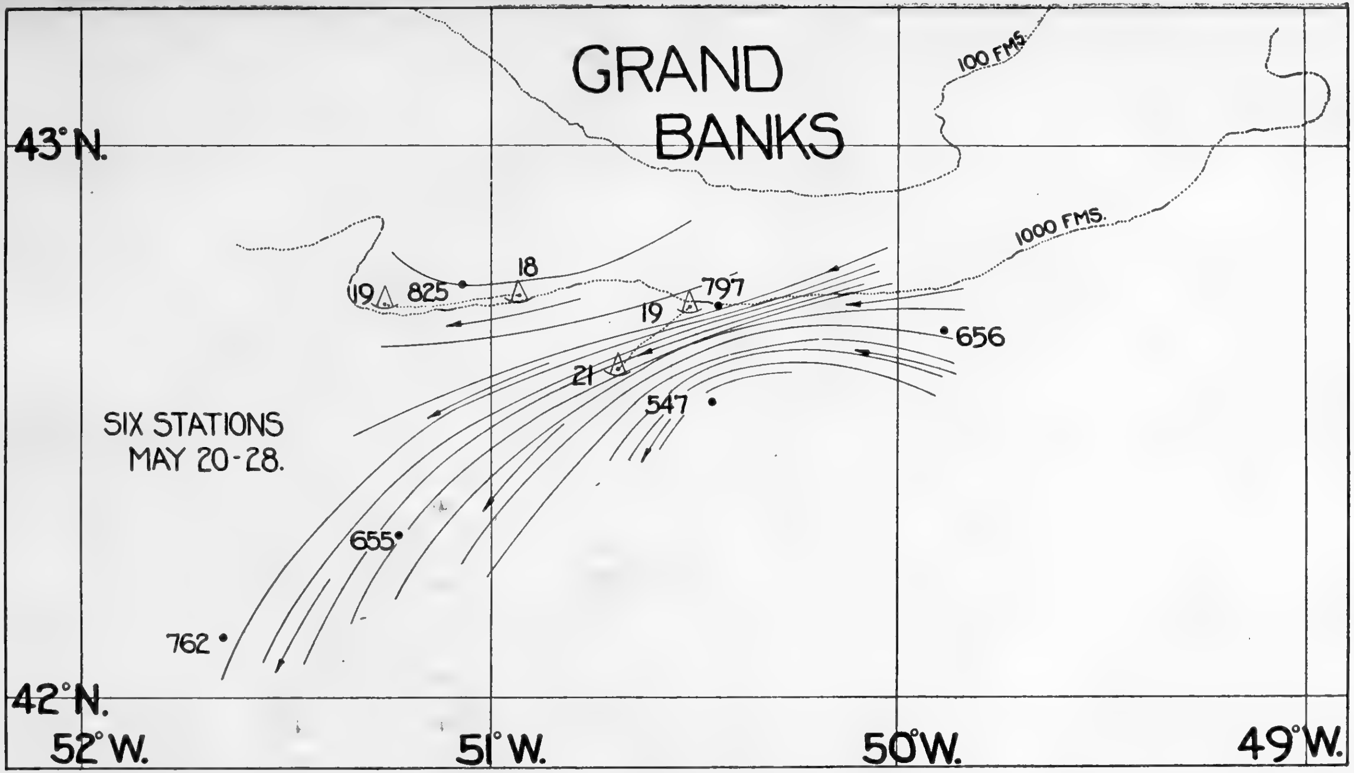

FIGURE 15.—Current map made from a group of stations occupied during May, 1929. Three-figure numbers near stations show in dynamic millimeters distance in excess of 728 dynamic meters from sea surface to 750-decibar pressure level. Great packing of contour lines between the two stations SSW. of the Tail probably due in part to the 8-day interval between their dates of occupation. At no time during May was a current of unusual strength observed in this locality

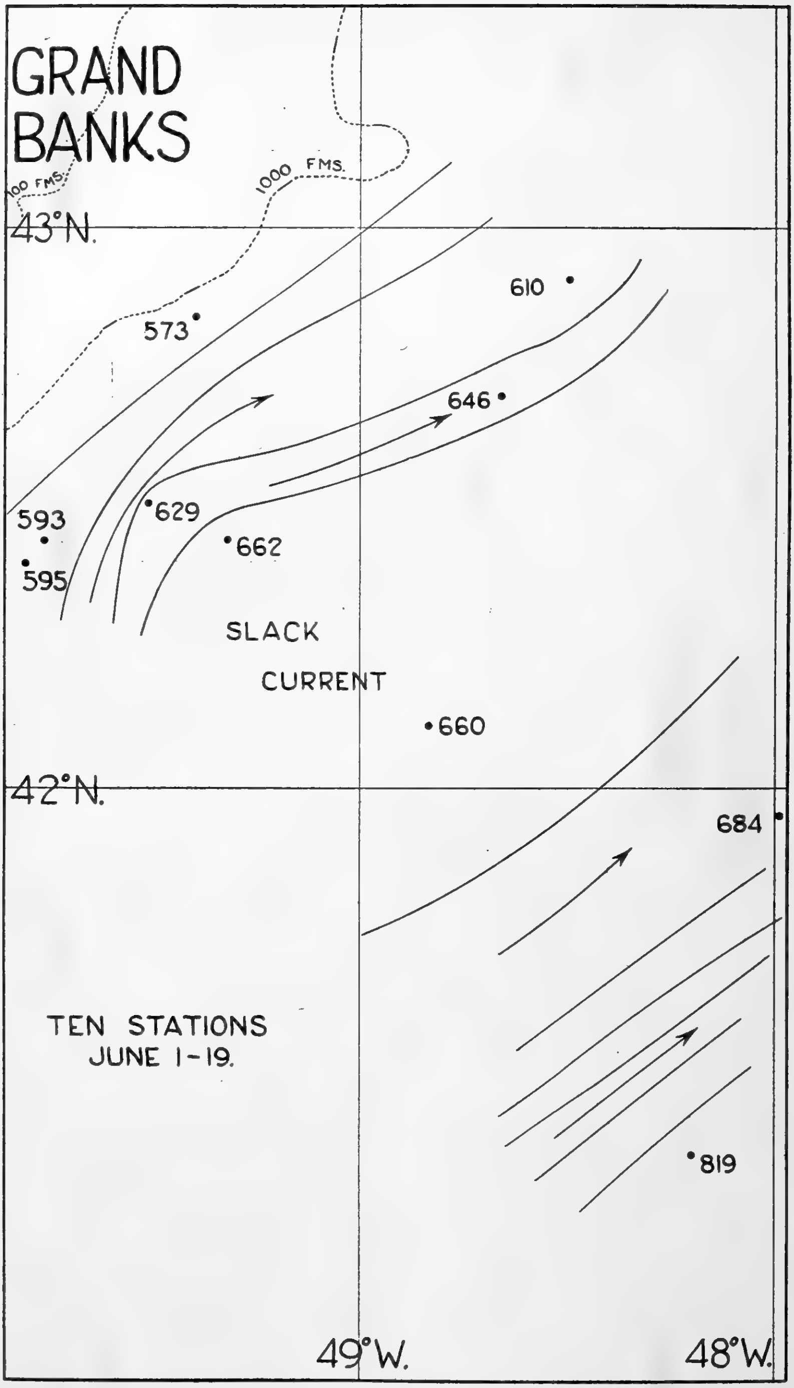

FIGURE 16.—Current map made from a group of stations occupied during June, 1929. The 3-figure numbers near stations show in dynamic millimeters the distance in excess of 728 dynamic meters from sea surface to 750-decibar pressure level. It appears from this map that two bands of current setting northeastward existed southeast of the Banks with an almost currentless area between them. Such slack waters do exist in fact off the Banks at times and bergs getting into them may remain almost stationary for several days

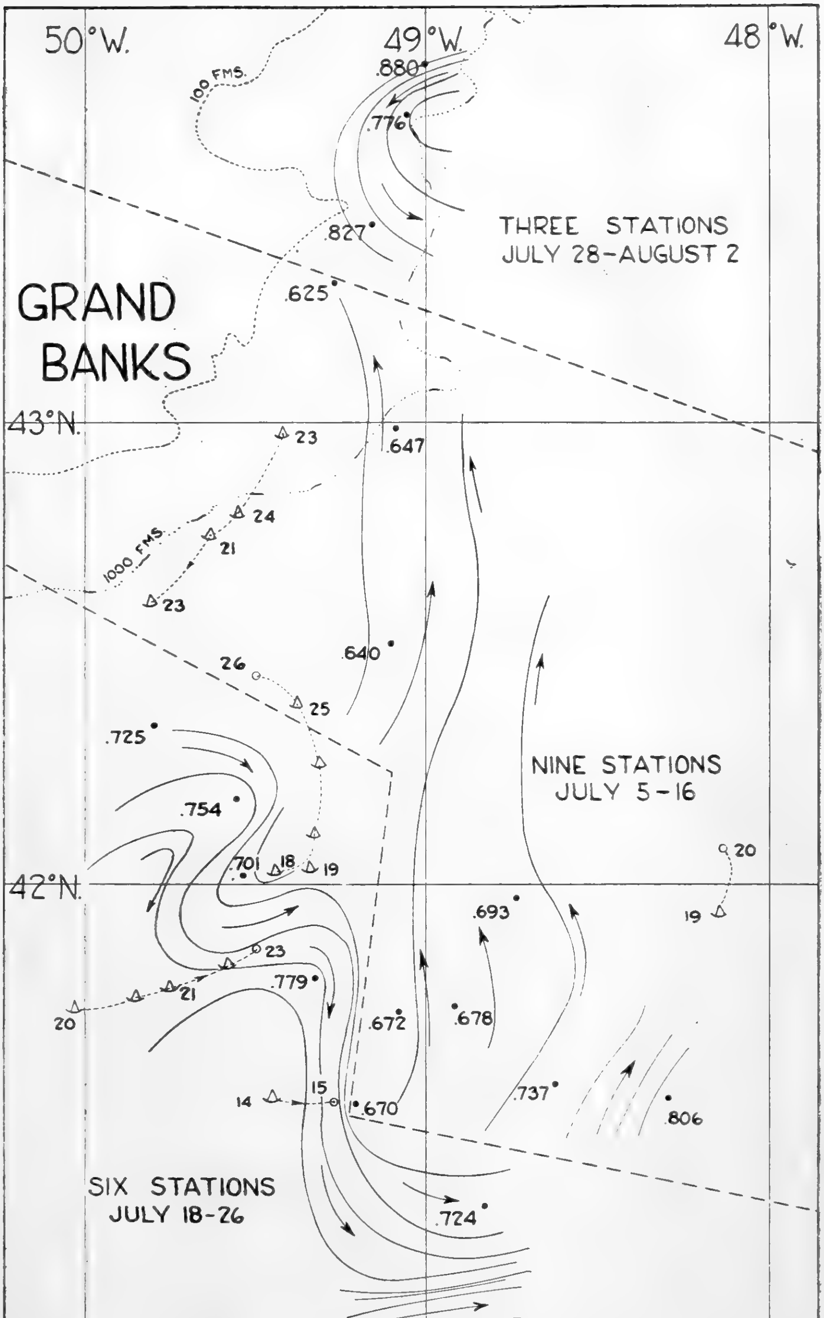

FIGURE 17.—Current map constructed from small groups of late season stations. Dashed lines show areas that are to be considered separately because of time-lapse factor. Three-figure numbers near stations show in dynamic millimeters distance in excess of 728 dynamic meters from sea surface to 750-decibar pressure level. A few known berg drifts are plotted to show relation between actual and dynamically determined currents

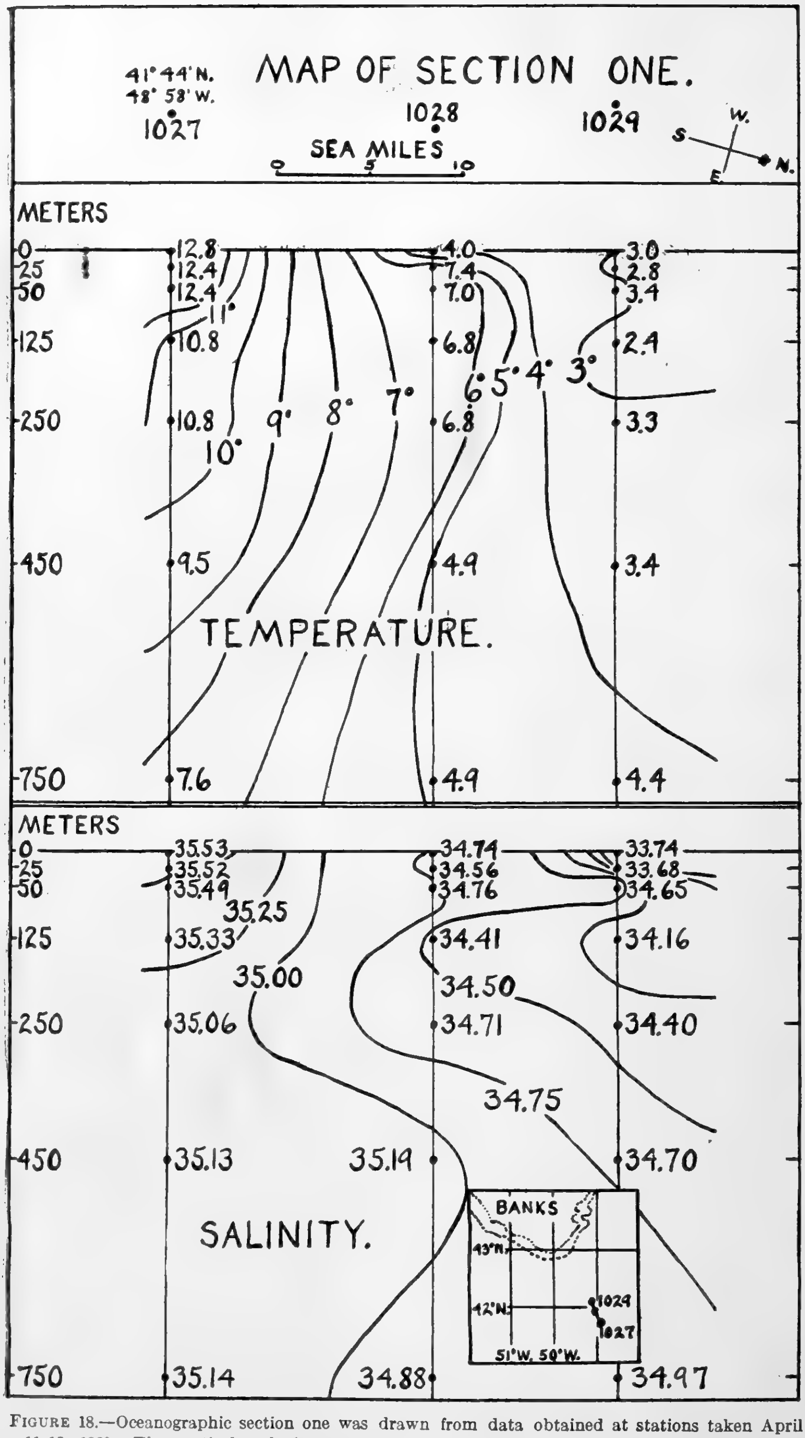

FIGURE 18.—Oceanographic section one was drawn from data obtained at stations taken April 11–12, 1929. The vertical scale is exaggerated about sixty times. Note very steep slope of isotherms and isohalines, characteristic of temperature wall

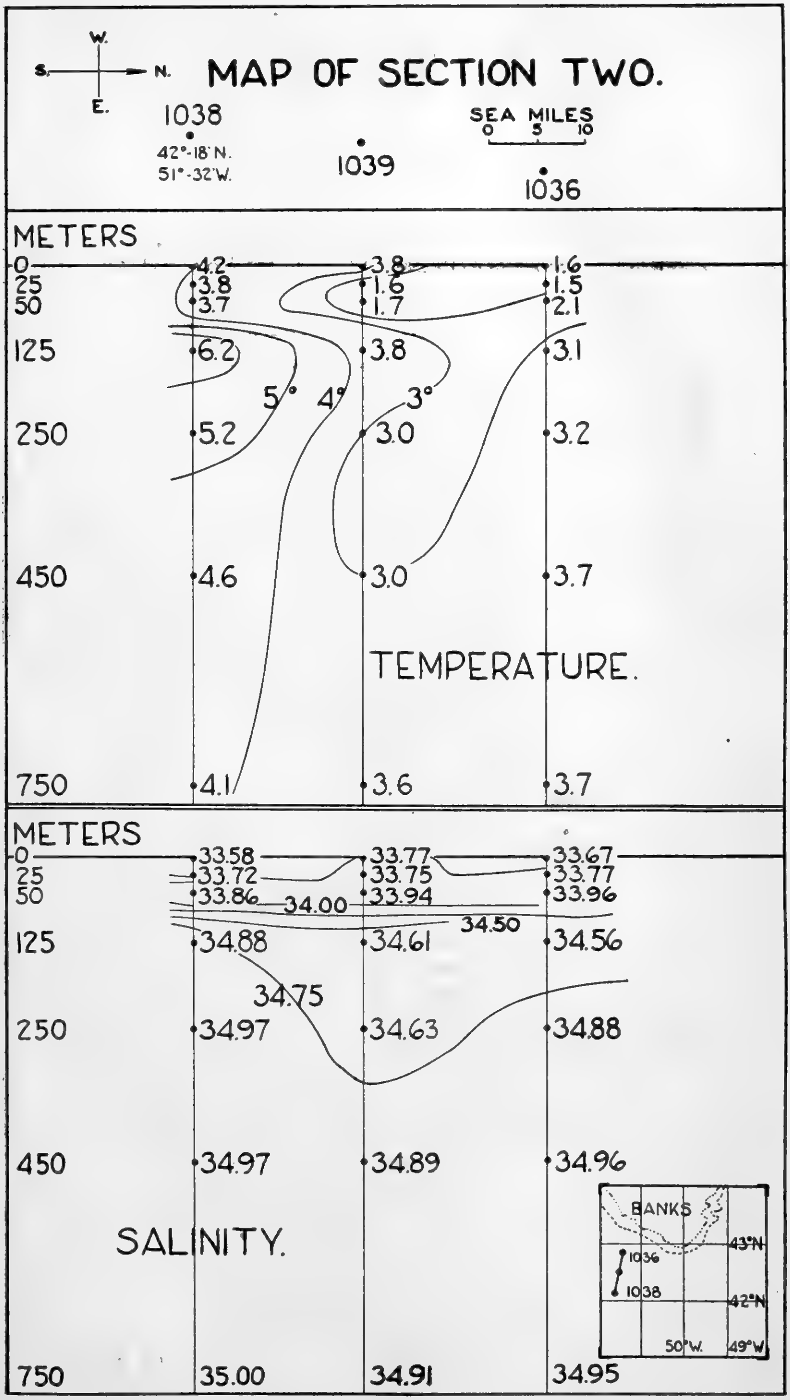

FIGURE 19.—Oceanographic section two was drawn from data obtained at stations taken April 23–26, 1929. The vertical scale is exaggerated about one hundred and twenty times. The salinity increases markedly with depth. This is characteristic of the cold and mixed waters about the Tail, where the Labrador Current overrides warmer Atlantic water of higher salinity

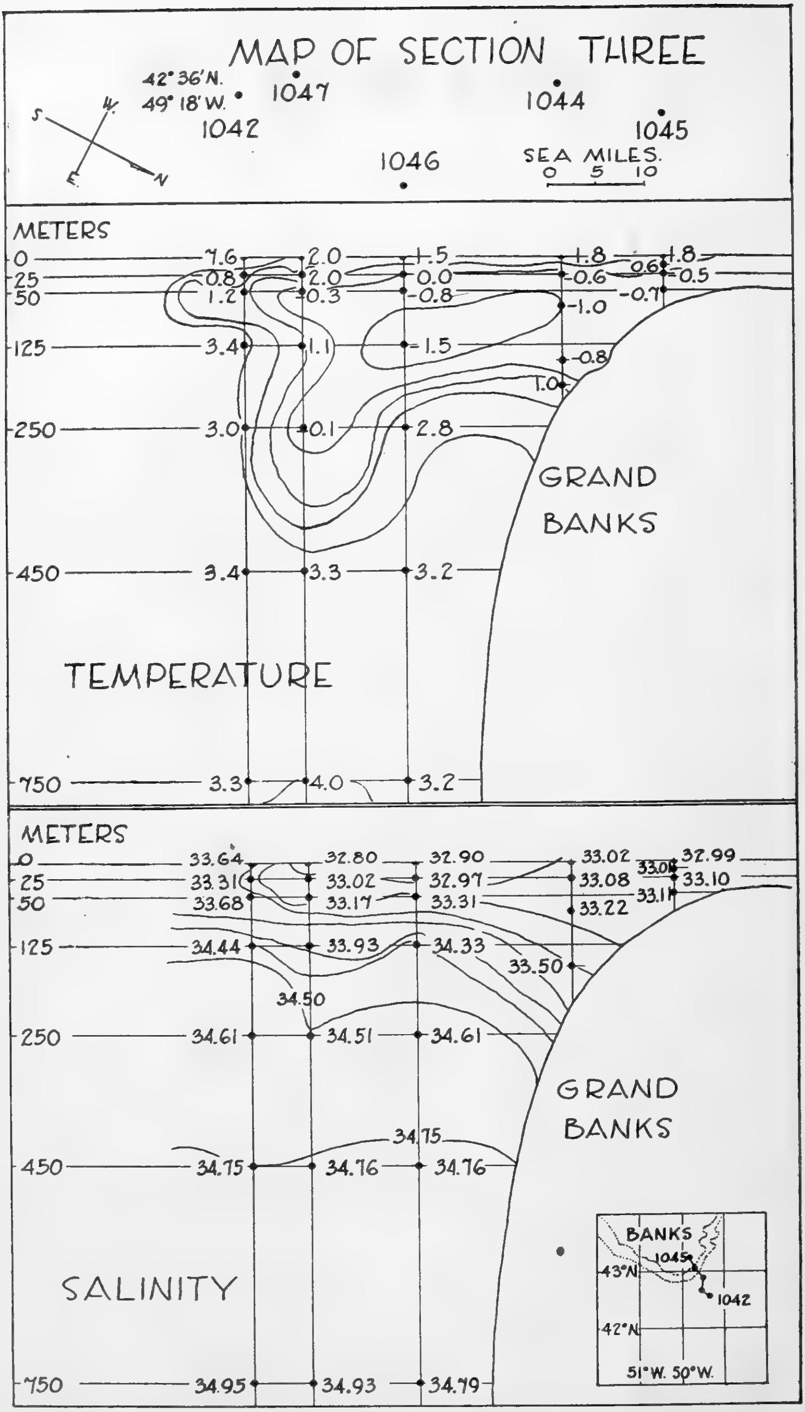

FIGURE 20.—Oceanographic section three was drawn from data obtained at stations taken May 6–11, 1929. The vertical scale is exaggerated about one hundred and twenty times. The salinity increases rapidly with depth. A cold-water layer between warmer surface and bottom waters can be seen. This is characteristic of the Labrador Current after the sun warms up the surface layers in the spring

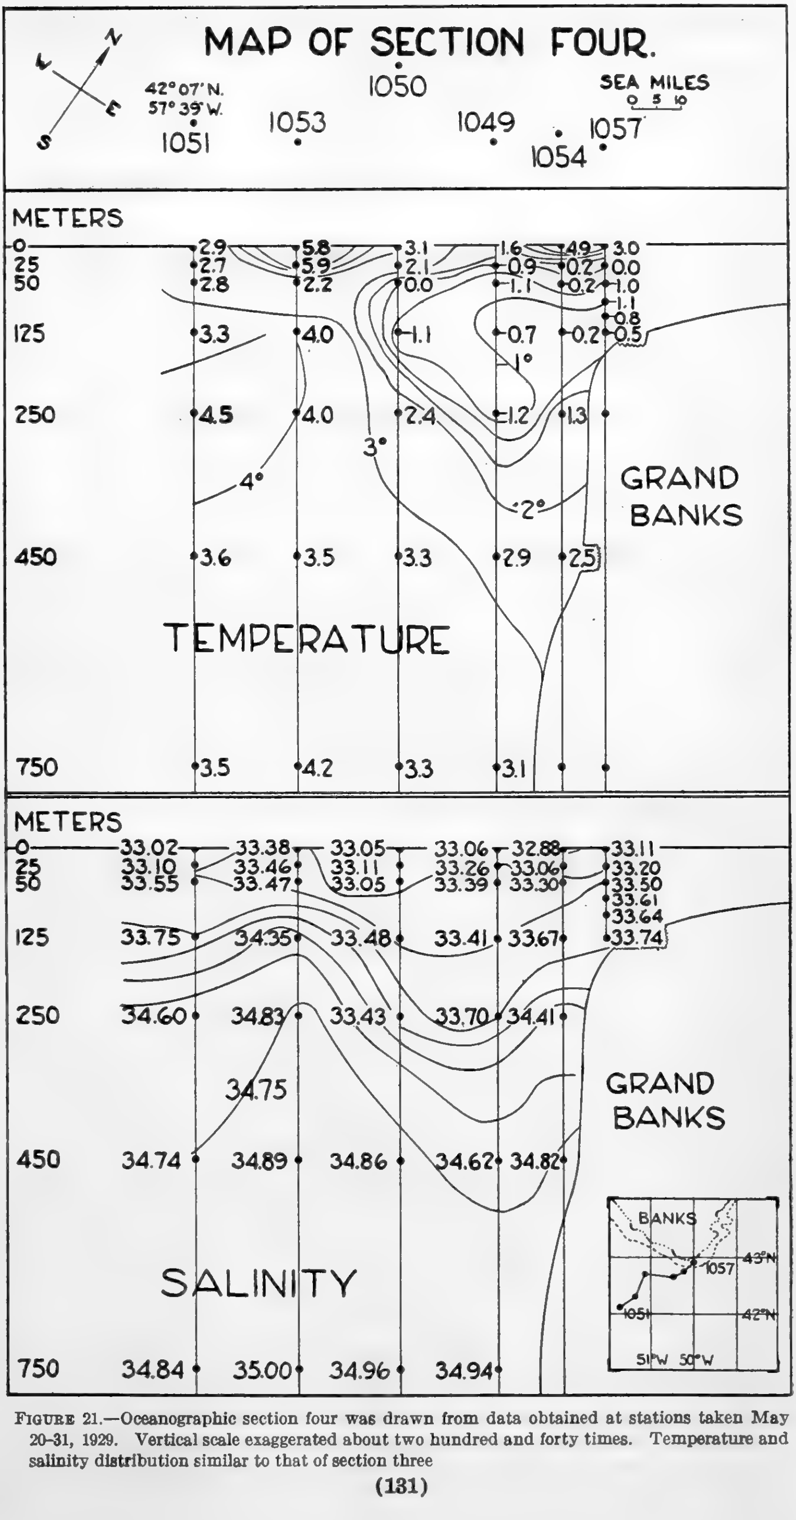

FIGURE 21.—Oceanographic section four was drawn from data obtained at stations taken May 20–31, 1929. Vertical scale exaggerated about two hundred and forty times. Temperature and salinity distribution similar to that of section three

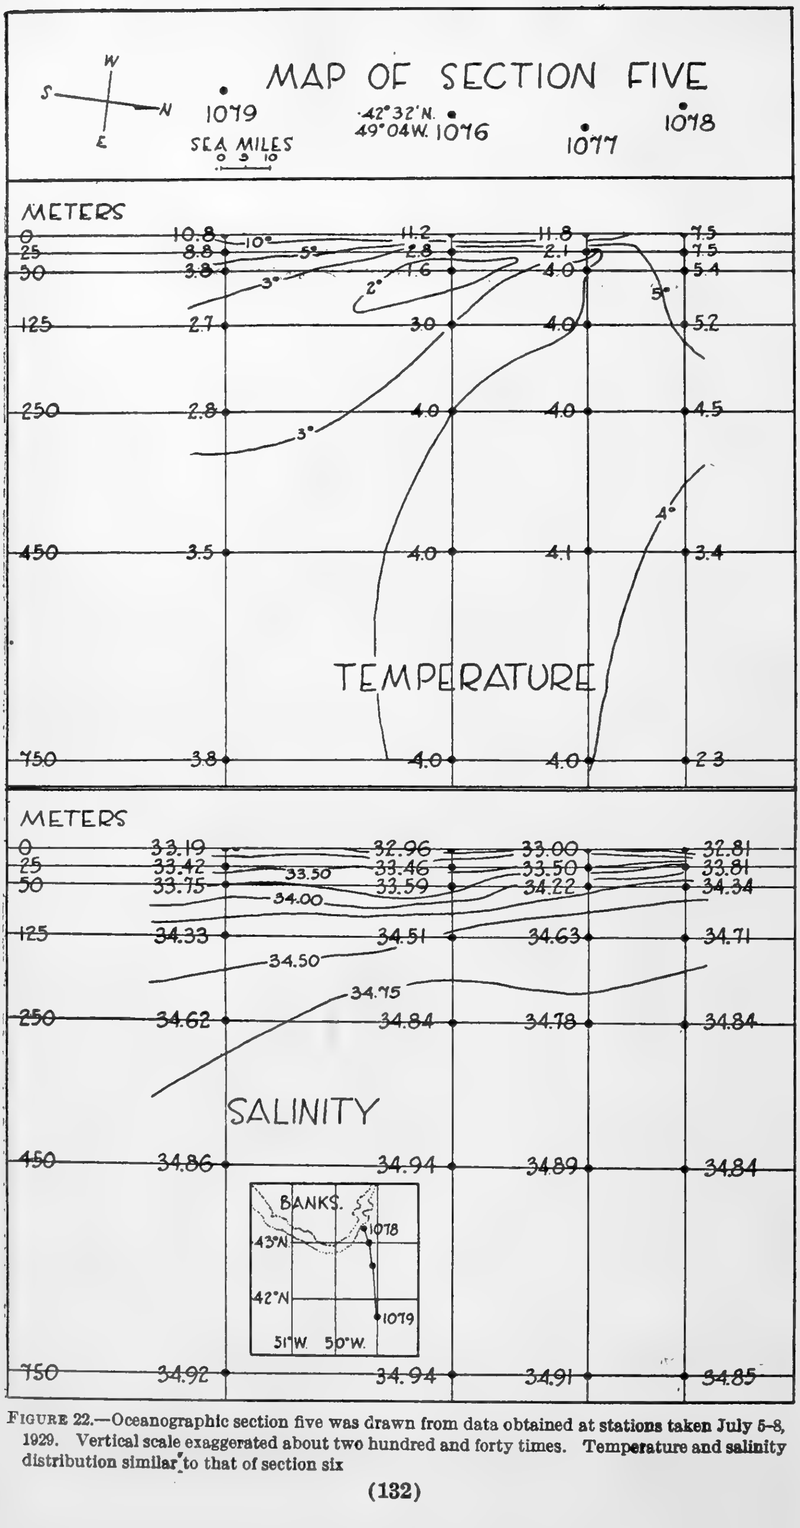

FIGURE 22.—Oceanographic section five was drawn from data obtained at stations taken July 5–8, 1929. Vertical scale exaggerated about two hundred and forty times. Temperature and salinity distribution similar to that of section six

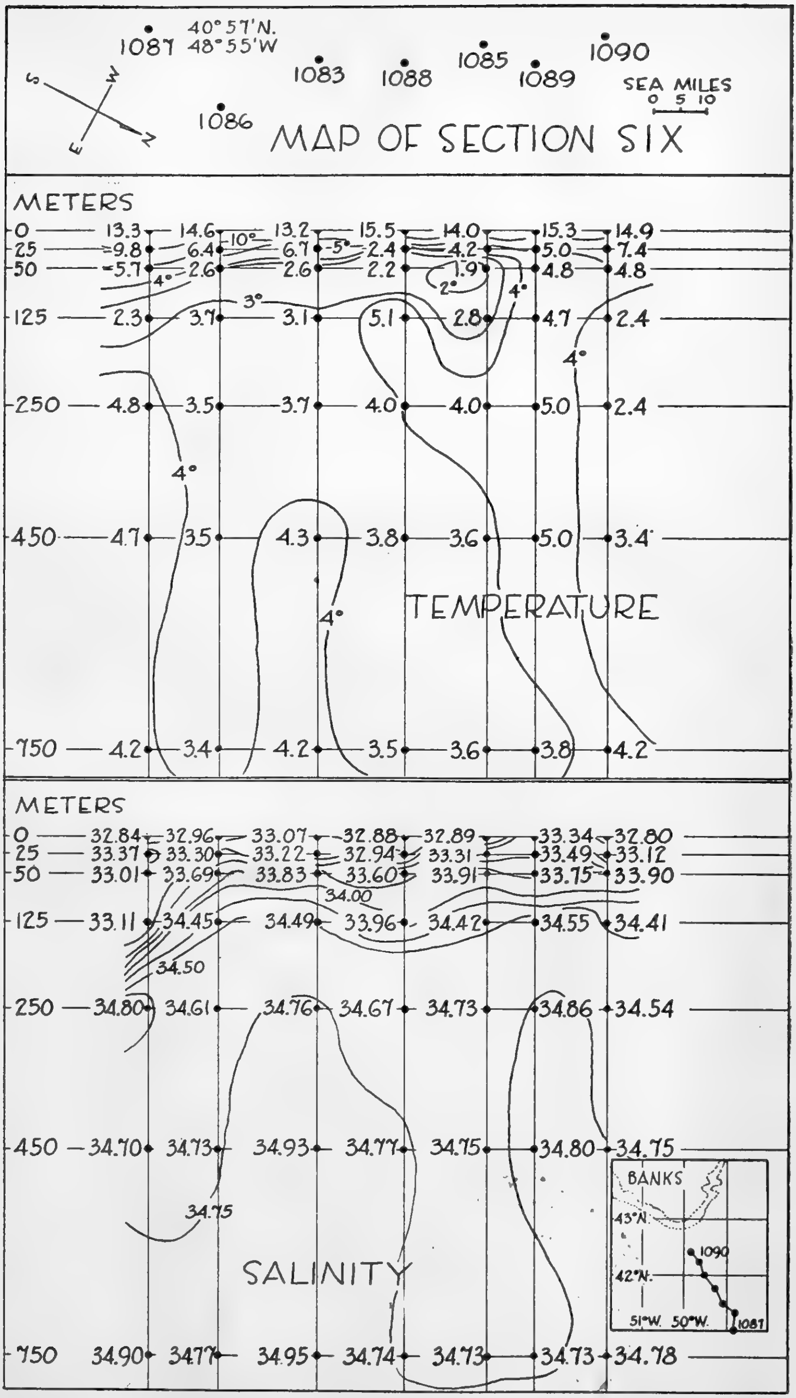

FIGURE 23.—Oceanographic section six was drawn from data obtained at stations taken July 15–26, 1929. Vertical scale exaggerated about two hundred and forty times. Surface layers much warmed. Salinity increases rapidly from surface to 200-meter level due to push of Labrador Current over North Atlantic mid-depth and bottom waters

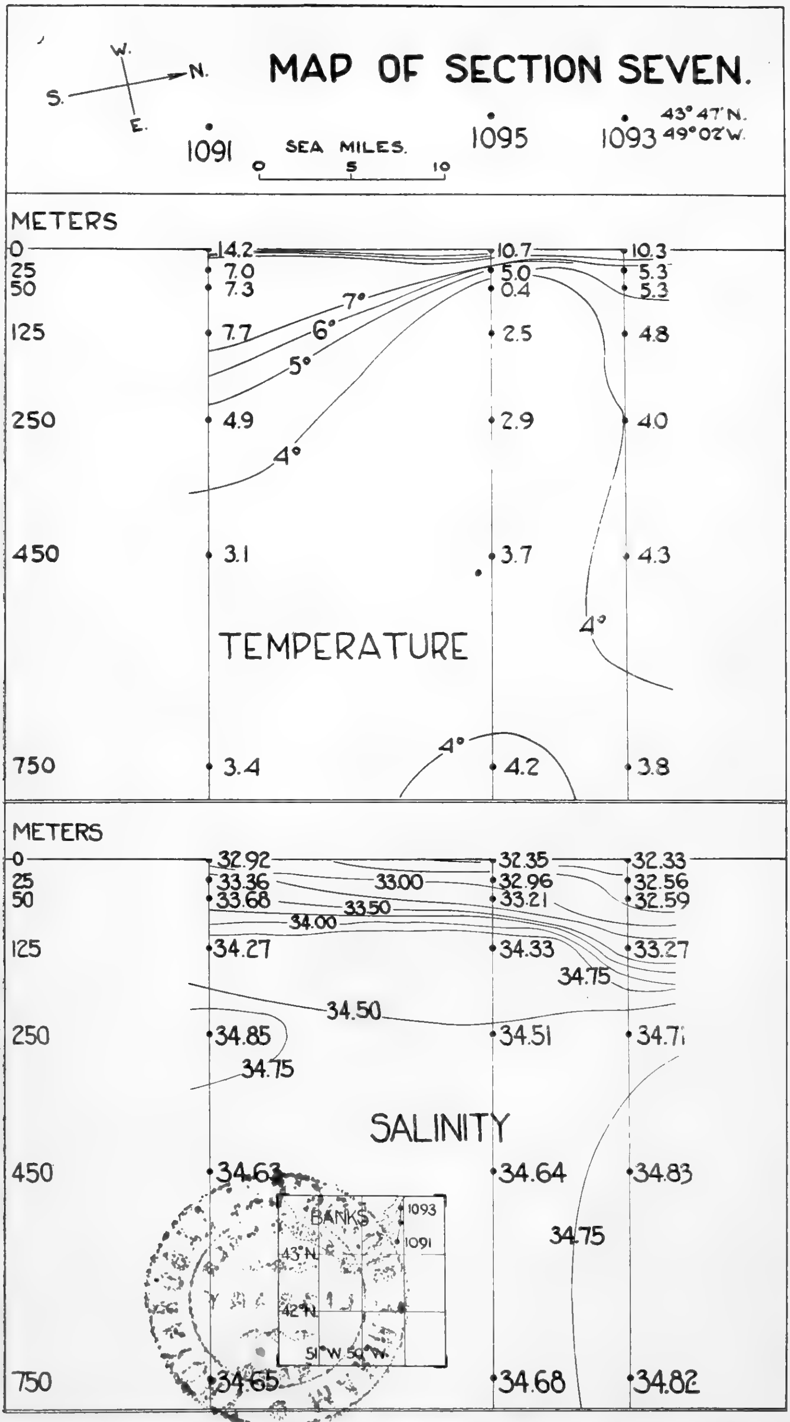

FIGURE 24.—Oceanographic section seven was drawn from data obtained at stations taken July 28 to August 2, 1929. Vertical scale exaggerated about sixty times. Temperature and salinity distribution similar to that of section six

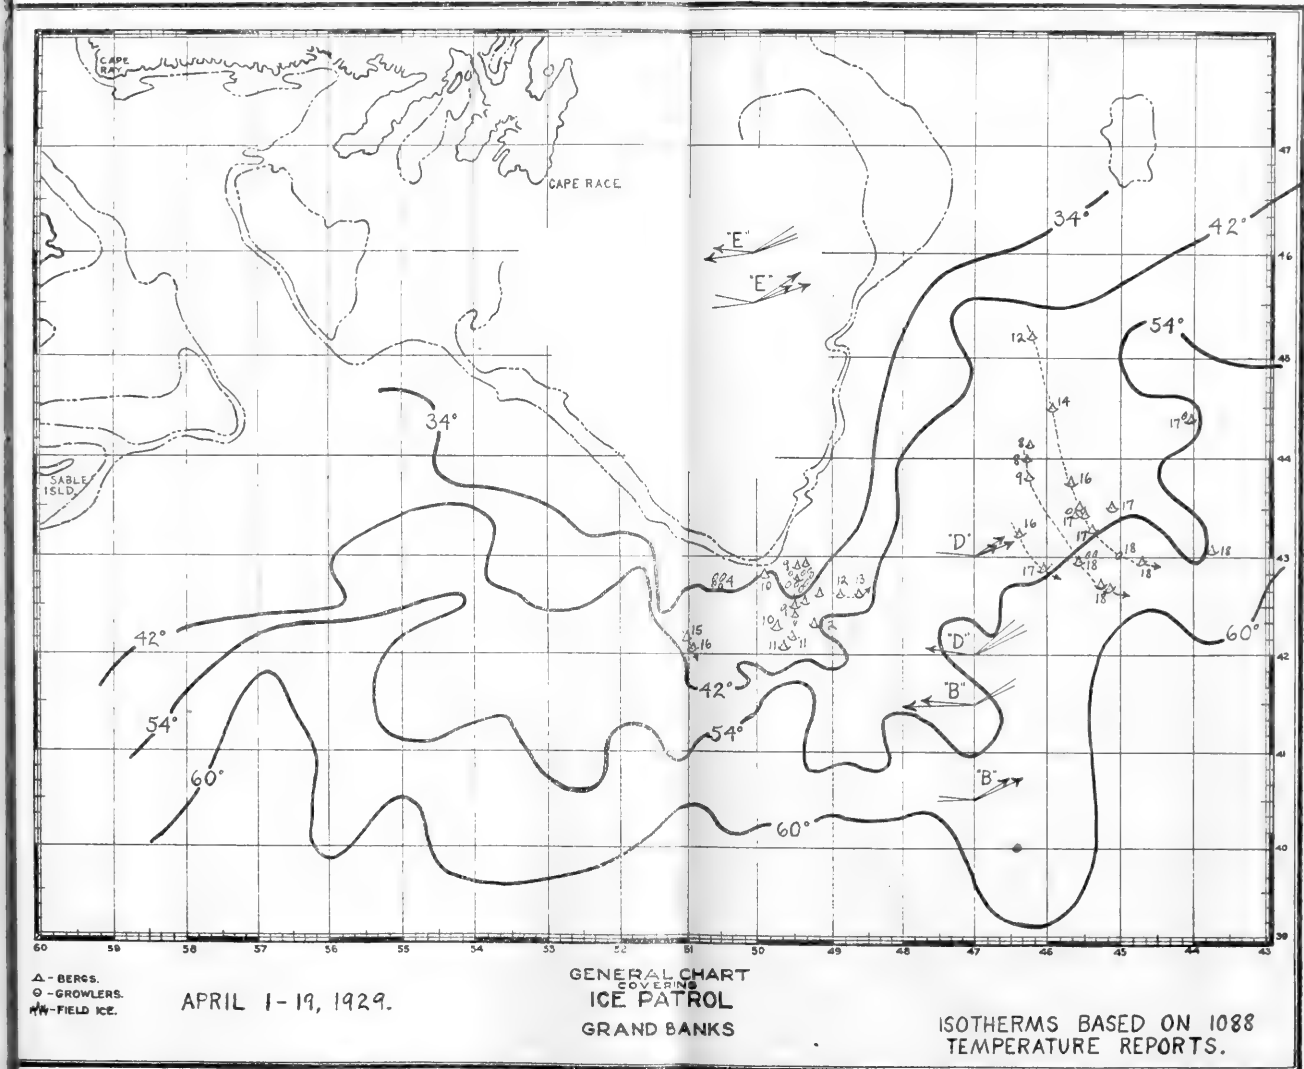

FIGURE 25.—Surface temperatures April 1-19, 1929. Portions of steamship tracks in use and southernmost ice are shown. Dotted lines connecting berg positions indicate probable drift tracks
